INTRODUCTION

Ionizing radiations such as gamma-rays and x-rays are radiations that have sufficient energy to displace electrons from molecules. These freed electrons then have the capability of damaging other molecules and, in particular, DNA. Thus, the potential health effects of low levels of radiation are important to understand in order to be able to quantify their effects. For example, it has been estimated that 10% of lung cancers are attributable to radon exposures. In recent years the amount of radiation that the public receives has greatly increased due to medical applications, especially the higher doses associated with computed tomography (CT) scans. Currently 50% of radiation exposures are from medical, 48% from environmental (primarily radon), and 2% from consumer products. The average yearly total effective exposure to individuals is 6.2 mSv. For an extensive analysis, the reader is referred to National Council on Radiation Protection (NCRP) Report 160 (NCRP, 2009). Fig. 25-1 taken from the report gives a summary breakdown of exposure sources.

Biological effects of radiation are primarily damage to the DNA. Atoms of the DNA target may be directly ionized or indirectly affected by the creation of a free radical that can interact with the DNA molecule. In particular, the hydroxyl radical is predominant in DNA damage. For radiation particles such as neutrons and α particles the damage is primarily direct, whereas for photons such as x-rays, about two-thirds of the DNA damage in mammalian cells is due to hydroxy radicals. The study of health effects of ionizing radiation is complicated by the fact that there are various types of radiation, from x-ray photons to heavy charged particles encountered in space. Within any type of radiation the potential damage also depends on the energy level of the photons or particles.

Cancer has been the major adverse health effect of ionizing radiation. It has been well studied epidemiologically, as well as in the laboratory and in animal toxicological studies. More recently, there has been a concern with possible cardiovascular effects, cataractogenesis, and possibly immunosenescence. At one time there was considerable concern about the possible heritable effects, but the risks now appear to be small. The issues with chemicals are the risks at low doses, and with radiation the effects of acute versus chronic exposures. Most radiation risk analyses depend on epidemiological studies. There have been many that have large populations and varied exposures. There is, however, a need for better radiobiological understanding of potential health effects in order to estimate low-dose effects, sensitive subgroups, and radiation types and energies that have not been adequately studied.

RADIATION BACKGROUND

Types of Ionizing Radiation

When ionizing radiation passes through matter, it has the energy to ionize atoms so that one or more of its electrons can be dislodged and chemical bonds broken. Ionizing radiation is of two types: particulate and electromagnetic waves. Particulate radiation may either be electrically charged (α, β, proton) or have no charge (neutron). Ionizing electromagnetic radiation (photons) in the form of x-rays or gamma-rays has considerably more energy than nonionizing radiation, such as ultraviolet and visible light.

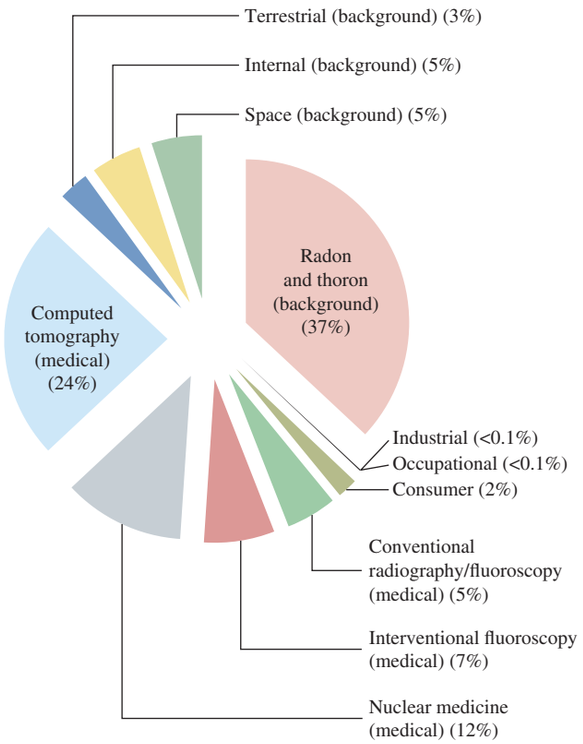

Figure 25-1. *Percent contribution of total effective dose to individuals (NCRP Report 160).*

Radionuclides (i.e., radioactive atoms), being unstable, release both electromagnetic and particulate radiation during their radioactive decay. The radionuclides decay into either stable elements or through a decay chain of successive radionuclides called decay daughters. The types of radiation emitted, its rate of decay, and the energies of the released radiation are unique to each type of radionuclide. The charged particles are directly ionizing because they ionize molecules by direct collisions with the molecules' electrons. Photons can travel relatively long distances, and after interacting with an electron in a material, the photon transfers some or all of its energy to the electron. The energetic electrons (i.e., photoelectrons or Compton electrons) are released, producing an indirect ionization. There are three basic radionuclide decay series: thorium, neptunium, and uranium series. The uranium decay series is illustrated in Fig. 25-2, and Table 25-1 gives the details.

The rate of energy dissipation by a single event is referred to as linear energy transfer (LET). The LET of a charged particle is the average energy lost due to interactions per unit length of its trajectory given as kiloelectron volts per micrometer (keV/μm). X-rays, gamma-rays, and β particles of similar energies produce sparse ionization tracks and are classified as low-LET radiation. Particulate radiation (e.g., neutrons and α particles) causes interactions with large amounts of energy being dissipated within short distances. Alpha particles (helium nucleus), which are released from the nucleus of some radionuclides, are slow-moving with a positive charge. Although they cannot penetrate a piece of paper or skin, they are of concern if ingested or inhaled. The most recognized example is the lung cancer risk from the inhalation of radon (Rn 222) and its daughter products. LET depends on the energy of the particle; for example, the LET of a 5-MeV α particle would be 100 keV/μm. Neutrons released during nuclear chain reactions have a greater range and lower LET (20 for a 2.5-MeV neutron). A 250-keV x-ray has an LET of 2 to 3 and a Cobalt 60 gamma-ray 0.2 to 0.3. A β particle is a simple electron that is released from the nucleus when a neutron converts into a proton, and it has similar low-LET values depending again on its energy.

The rate of decay of a radionuclide is exponential with a decay rate constant λ that is then simply $Ae^{-\lambda t}$ for time t and initial quantity of the radionuclide A. The radiological half-life is the time required for the radionuclide to lose 50% of its activity by decay. Each radionuclide has its own unique half-life as illustrated in Table 25-1. For example, the half-life of iodine 131 is 8 days while for cesium 137 it is 20 years. If a radionuclide is internally deposited in an individual, the actual half-life is obtained by taking the reciprocal of the sum of the reciprocals of the radiological half-life and the biological half-life; that is, $1/T = 1/T_r + 1/T_b$ where T is the half-life, T_r is the radiological half-life, and T_b is the biological half-life. For more extensive and detailed information the reader is referred to Biological Effects of Ionizing Radiation (BEIR) VII and the text by Turner (2007).

Relative Biological Effectiveness and Quality Factors

The various types of ionizing radiation have similar biological effects that occur because of the ionization of molecules. However, without knowing the type of radiation, one cannot specify how much radiation is needed to produce a specific biological effect. This is because a given absorbed dose (energy per unit mass) of x-rays does not have the same biological effect as an identical dose of neutrons. The relative effectiveness of different types of radiation in producing biological changes depends on deposition of energy, that is, LET. In order to deal with this problem the International Council of Radiation Protection (ICRP) developed the concept of relative biological effectiveness (RBE). It is defined in BEIR V as follows:

Biological potency of one radiation as compared with another to produce the same biological endpoint. It is numerically equal to the inverse of the ratio of absorbed doses of the two radiations required to produce equal biological effects. The reference radiation is often 200-kV x-rays.

The difficulty is that the RBE may differ depending on the biological endpoint and it may also be dose-dependent. When dose is not specified, it is assumed that the RBE is at the low-dose limit (see BEIR VII). The RBE increases as a function of LET, reaching a maximum at about 100 keV/μm. Interestingly, it was pointed out by Hall and Giaccia (2005) that at the density of ionization of 100 keV/μm, the average separation between ionization events just coincides with the diameter of the DNA double helix. Thus, radiation with this density has the highest probability of causing a double-stranded break by the passage of a single charged particle.

For regulatory purposes, the ICRP introduced the related concept of "quality factor" (Q) or weighting factor w_R. It is defined as an LET-dependent factor by which doses are multiplied to obtain a quantity that corresponds to the degree of biological effect produced by x-rays and low-energy gamma-rays. Table 25-2 gives the current weighting factors, whereas Fig. 25-3 plots the values for various neutron energy levels (taken from ICRP 103; ICRP, 2007).

The "equivalent dose" to an organ or tissue is then defined as $H_T = \Sigma_R w_R D_{TR}$ where D_{TR} is the dose to the organ from radiation type R. For public health purposes, ICRP further defines "effective dose" as $E = \Sigma_T w_T H_T$ where w_T are tissue-weighting factors (Table 25-3). It should be noted that these are the currently recommended

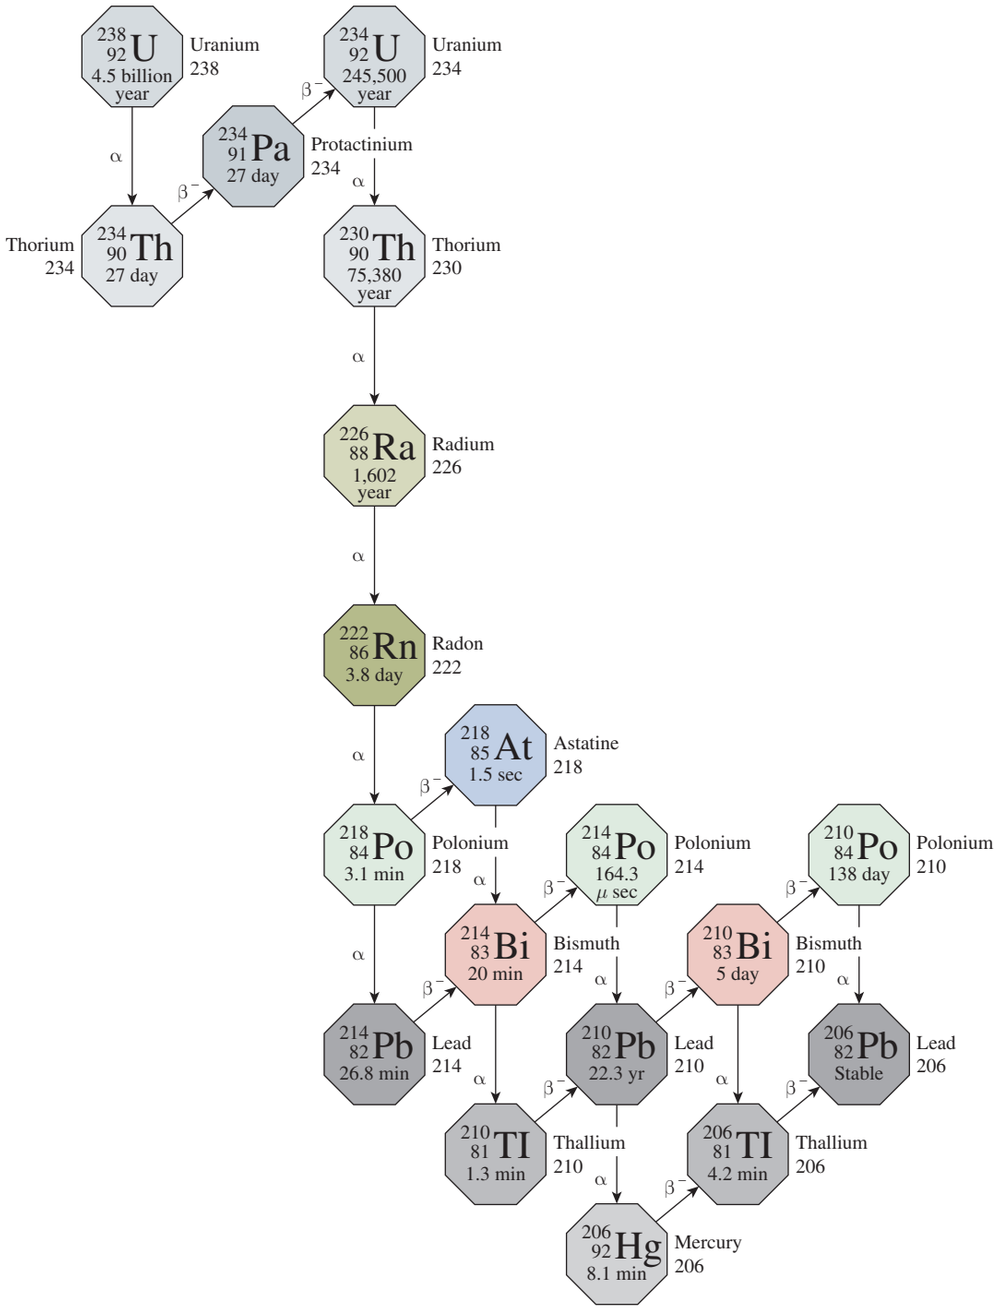

Figure 25-2. *Uranium decay chain.*

ICRP values although the Nuclear Regulatory Agency is using previous values (e.g., 0.25 instead of 0.08 for gonads possibly because of previous concerns about genetic effects). For the radionuclides there are also the terms "committed equivalent dose" and "committed effective dose," which simply means the total accumulative dose for 50 years after the exposure. Finally "total effective dose equivalent" (TEDE) means the sum of the effective dose equivalent (for external exposures) and the committed effective dose equivalent (for internal exposures).

Units of Radiation Activity and Dose

The basic unit of radiation activity is the Becquerel (Bq), which is nuclear disintegrations per second. The older unit of activity is the Curie (Ci), which corresponds to the number of disintegrations in 1 second from 1 g of radium 226 or 1 Ci = 3.7×10^{10} decays per second; thus, 1 Bq = 2.7×10^{-11} Ci. The EPA continues to use the old unit of activity with regard to radon. For example, the EPA's level of concern for radon in the home currently is 4 pCi/L, which is equivalent to 148 Bq/m^3.

Table 25-1

Radioisotopes in the Uranium Decay Series

NUCLIDE	DECAY MODE	HALF-LIFE (a = YEAR)	ENERGY RELEASED (MeV)	PRODUCT OF DECAY
^{238}U	α	4.468 × 10^{9}a	4.270	^{234}Th

Table 25-2

Recommended Radiation Weighting Factors

RADIATION TYPE	RADIATION WEIGHTING FACTOR (W_R)
Photons	1
Electrons and muons	1
Protons and pions	2
Alpha particles, fission fragments, heavy ions	20
Neutrons	See Fig. 25-3

The "equivalent dose" to an organ or tissue is then defined as $H_T = \Sigma_R w_R D_{TR}$, where D_{TR} is the dose to the organ from radiation type R. For public health purposes.

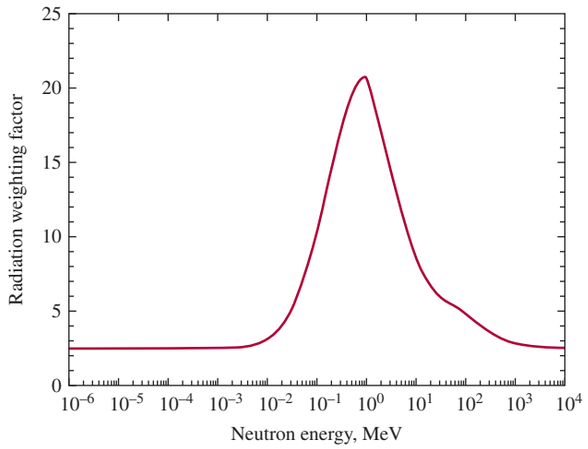

Figure 25-3. *Neutron weighting factor by energy level.*

The basic unit of dose is the Gray (Gy), which is the amount of energy released in a given mass of tissue. One Gray is defined as 1 joule of energy released in 1 kg of tissue. The older dose unit of rad (100 erg/g) is 1/100 of a Gray. The other common measure is the Sievert (Sv), which is a dose equivalent; that is, the dose in Gray multiplied by the appropriate quality factor. The dose equivalent rem is rad multiplied by the quality factor. Because ^{60}Co gamma-rays and 240 keV x-rays have a quality factor of one, we see Sv and Gy are used interchangeably in studies. Less common is the roentgen (R) that quantifies exposure, and is the number of ionizations in a cubic meter of air produced by x-rays or gamma radiation. Because 1 roentgen of gamma- and x-ray gives an absorbed dose to tissue of about 1 rad (10 mGy), they are nearly equivalent. For radon and its daughters, a different exposure system is used. Considering the uranium miner studies, exposure is expressed as a working level (WL), which is defined by BEIR VI as follows:

Any combination of the short-lived progeny of radon in 1 L of air, under ambient temperature and pressure, that results in the ultimate emission of 1.3 × 10^5 MeV of α particle energy. This is approximately the total amount of energy released over a long period of time by the short-lived progeny in equilibrium with 100 pCi of radon. 1 WL = 2.08 × 10^{-5} Jm^{-3}.

For cumulative exposure, a working level month (WLM) is used, which is the exposure to 1 WL for 1 working month of 170 hours.

Table 25-3

Recommended Tissue Weighting Factors

TISSUE	W_T	$\Sigma_T W_T$
Bone-marrow, colon, lung, stomach, breast, remainder tissues*	0.12	0.72
Gonads	0.08	0.08
Bladder, esophagus, liver, thyroid	0.04	0.16
Bone surface, brain, salivary glands, skin	0.01	0.04
	Total	1.00

**Remainder tissues: adrenals, extrathoracic (ET) region, gall bladder, heart, kidneys, lymphatic nodes, muscle, oral mucosa, pancreas, prostate, small intestine, spleen, thymus, and uterus/cervix.*

RADIOBIOLOGY

Radiation biology has made significant progress in our understanding of radiation effects at low doses. BEIR VII and, more recently, Dauer et al. (2010) go into great detail describing our current knowledge as it pertains to radiation-induced cancer. Currently radiation cancer risk extrapolations make two assumptions: namely that the basic mode of action is linearly related to dose and that the individual cell is the unit of risk. However, effects occurring in nontargeted cells, such as with induced genomic instability and bystander effects, suggest that responses can occur nonuniformly over time at the tissue level. How cells in tissues react to radiation effects is not well understood. There are many complexities in the cancer process that are not explained by the "single-cell biophysical hit" model of radiation-induced cancer, which is the basis for the linear no-threshold (LNT) model used for low-dose cancer risk assessments. Damage from ionizing radiation appears to increase linearly with dose, but recent data suggest that the processing and repair of induced damage could be nonlinear. The understanding of these processes is necessary for low-dose risk estimation. Following irradiation, various protective cellular processes occur that depend on the degree of damage and the tissue type. These mechanisms include DNA repair, intracellular metabolic oxidation/reduction reactions, cell cycle checkpoint controls, cellular signaling, senescence, and apoptosis (see Dauer et al., 2010).

The BEIR VII report reviewed in detail the effects of DNA damage after exposure to low doses of ionizing radiation. After an exposure to 5 mGy of low-LET radiation (average background per year), each cell nucleus is on average hit by one electron, resulting in 5 to 10 damaged bases, 2.5 to 5 single-strand breaks and 0.25 double-strand breaks.

Nontargeted Radiation Effects

Exposure to ionizing radiation can result in direct damage to the irradiated cells as well as producing effects in cells that were not irradiated (bystander effects). These nontargeted effects can occur in the nonirradiated neighbors of irradiated cells and at sites distant from the irradiated cells. Effects can also be observed in the progeny of an irradiated cell (genomic instability). Both targeted and nontargeted effects can result in DNA mutations, gene amplifications, chromosomal rearrangements, carcinogenesis, and cell death.

Bystander Effects Radiation-induced bystander effects are those in which cells that have not been directly exposed to ionizing radiation react as though they have been exposed by receiving a biochemical signal from a radiation-exposed cell. That is, they show chromosomal instability and other abnormalities, or die. BEIR VII concluded that for high-LET radiation a bystander effect has been shown for inducing cell lethality, chromosome aberrations, sister-chromatid exchanges, mutations, genomic instability, signal transduction pathways, and in vitro transformation. For low-LET radiation, the bystander effect has been limited to cell lethality and lethal mutations.

These bystander cells can be either adjacent or at some distance from the radiation-exposed cell. Not all cells can produce bystander signals or react to them. The important issue from a risk assessment view is whether bystander effects are beneficial (e.g., adaptive response and apoptosis [removal of damaged cells]) or detrimental to the nonexposed cells, and what impact they may have on dose response at low doses. It should be noted that most observed effects are detrimental, but beneficial effects are more difficult to measure. However, bystander effects demonstrate that the organism and tissues communicate and are responding as an organized structure to radiation insult. Large DNA deletions are the major type of radiation-induced mutations. In bystander cells, however, the types of mutations are similar to those that occur spontaneously, with the majority being point mutations. These differences are important in understanding risk at low doses (Dauer et al., 2010).

BEIR VII quotes Sawant et al. (2001) on high-LET bystander in vitro studies that "These results, if applicable in vivo, would have significant consequences in terms of radiation risk extrapolation to low doses, implying that the relevant target for radiation oncogenesis is larger than an individual cell, and that the risk of carcinogenesis would increase more slowly, if at all, at higher doses—an effect seen in vivo, as well as epidemiologically. Thus, a simple linear extrapolation of radiation risk from high doses (where they can be measured) to lower doses (where they must be inferred) would be of questionable validity." In other words, it is speculated that there could be a convex, downward-curving dose–response relationship at low doses, and that extrapolation of data from high doses could lead to an underestimate of the effect at low doses of high-LET radiation. Finally, BEIR VII concludes that "until molecular mechanisms of the bystander effect are elucidated, especially as related to an intact organism, and until reproducible bystander effects are observed for low-LET radiation in the dose range of 1 to 5 mGy, where an average of about one electron track traverses the nucleus, a bystander effect of low dose, low-LET radiation that might result in a dose–response curving either upward or downward should not be assumed." For an in-depth review of bystander effects both in vitro and in vivo see the papers by Morgan (2003a, 2003b) as well as Mothersill and Seymour (2004, 2005) and Liu et al. (2006).

Genomic Instability Genomic instability has been defined as the increase in rate of acquiring genetic change, and induced genomic instability can be observed in the progeny of irradiated cells and can persist for many generations (Morgan, 2003a, 2003b). When a cell is saturated in repairing radiation damage it may change its gene-product profile without any specific genetic damage. This has been suggested as a cause of genomic instability, which is an anti-inflammatory response, and is a risk for malignancy (Barcellos-Hoff, 2005). There is a need for the understanding of the molecular targets and processes responsible for genomic instability in order to understand the dose–response and why the frequency saturates at 10% to 30% of the surviving cells. This may be due to the fact that only a fraction of cells in a particular part of the cell cycle is susceptible. It is believed that genomic instability could be linked to the loss of telomere maintenance and too short telomeres as a mechanism in cancer development. Chromosome instability can also be initiated by double-strand breaks that result in the loss of a telomere that protects the chromosome end and prevents chromosome fusion. The induction of chromosomal aberrations plays an important role in genomic instability. There is also some evidence that reactive oxygen species (ROS) may play a role. BEIR VII concludes, "However, until the molecular mechanisms responsible for genomic instability and its relationship to carcinogenesis are understood, extrapolation of the limited dose–response data for genomic instability to radiation-induced cancers in the low-dose range <100 mGy is not warranted."

Adaptive Response Cells that are exposed to a low priming dose of radiation (e.g., 10 to 20 mGy) followed in a short time interval with a larger challenge dose (e.g., 1 Gy), the frequency of chromosomal aberrations induced by the challenge dose was found to be less than that from the challenge dose given alone. This effect is referred to as "adaptive response" (Tapio and Jacob, 2007). Studies have also shown that low doses of radiation may reduce the biological background effect. This has been shown for cell transformation

and chromosomal damage. It has also been observed that the normal rate of cell transformation (Redpath, 2006) and chromosome damage can be decreased to below the normal background level after an initial low-dose radiation exposure. Adaptive responses have been observed both in vitro and in vivo for both cancer and genetic effects, which suggests that low doses may decrease radiation risk. These adaptive responses suggest that enhancing normal repair or protective processes make it possible to decrease the risk for low-dose radiation-induced cancer (Dauer et al., 2010).

In BEIR VII's assessment of adaptive response, they state that data are needed when both the priming and challenging doses are low (less than 100 mGy) and when doses are delivered over several weeks or months at low dose rates or with fractionated exposures. They also suggest that the adaptive response studies using malignant transformation assays using immortalized cell lines may not be relevant to normal nonimmortalized cells. Finally BEIR VII states, "Thus, it is concluded that any useful extrapolations for dose–response relationships in humans cannot be made from the adaptive responses observed in human lymphocytes or other mammalian cellular systems. Therefore, at present, the assumption that any stimulatory effects of low doses of ionizing radiation substantially reduce long-term deleterious radiation effects in humans is unwarranted."

Hormesis

The BEIR VII committee defined hormesis as "the stimulating effect of small doses of substances which in larger doses are inhibitory" (see Calabrese et al. [2007] for a review). The committee concluded that the preponderance of available experimental data does not support the idea that low levels of ionizing radiation have a beneficial effect, and the possible mechanisms remain obscure. Further, they state, "At this time, the assumption that any stimulatory hormetic effects from low doses of ionizing radiation will have a significant health benefit to humans that exceeds potential detrimental effects from radiation exposure at the same dose is unwarranted." Research actively continues in this area and the BEIR committee recommends the need for research on the possible mechanisms for hormesis at low radiation doses.

Gene Expression

Gene expression profiling for monitoring ionizing radiation exposure has become an active area of research. It has been shown that dose, dose rate, radiation quality, and time since exposure result in variations in the response of genes, so that gene expression signatures may be markers of radiation exposure. Changes in gene expression in human cell lines occur after as little as 0.02 Gy gamma-rays (Amundson and Fornace, 2001; Amundson et al., 2003). Using gene expression methods, Ory et al. (2011) and Ugolin et al. (2011) were able to distinguish a number of post-Chernobyl thyroid tumors and postradiotherapy thyroid tumors from their sporadic counterparts. These techniques, if applicable to low-dose radiation exposures, could be very useful in radiation epidemiological studies (see Maenhaut et al., 2011).

Summary

Cancer being the primary health concern from exposure to ionizing radiation, there is a focus on mechanisms and dose–response as they relate to the induction of chromosomal aberrations and gene mutations because cancer is believed to be associated with these cellular responses. Experimental data indicate that the dose–response relationship over a range of 20 to 100 mGy is most likely to be linear, and not significantly affected by either an adaptive or a bystander effect. Data in this dose range for genomic instability are generally not available. The question of the shape of the dose–response relationship up to 20 mGy remains uncertain. The future of understanding low-dose radiation cancer risks will depend on the continued advancement of molecular biology, gene expression analysis, and computational biology.

CANCER EPIDEMIOLOGY

Epidemiological studies have been extensive and provide the basis for our understanding of radiation-induced cancer effects. These studies provide a wide range of exposures including populations at high natural background exposures, occupational studies, populations exposed to nuclear testing and reactor accidents, A-bomb survivor studies, and the follow-up of patients having had high-dose medical radiation therapies. Radiation cancer studies are no different from other types of occupational and environmental cancer studies in that radiation-induced cancers are not distinguishable pathologically, and there are usual issues of exposure confounding, long latencies (e.g., 10 to 20 years for solid tumors), levels of exposure, and study size. Generally for acute exposures only epidemiological studies with exposures to relatively high doses of radiation (greater than 0.15 Sv) have shown such an excess of cancer. Because of these difficulties, the most informative studies are those that involve a large number of individuals with large radiation doses and follow-up of several decades.

Epidemiological assessment of cancer in populations exposed to radiation has been the principal source of information used by regulatory groups. The National Academies series of BEIR reports provides this information through expert committee analyses. The most recent report BEIR VII is restricted to the health effects of low-LET radiation (e.g., gamma-ray and x-ray). The BEIR VI report is solely devoted to radon, whereas BEIR IV is focused on radionuclides. BEIR V is a previous version of BEIR VII. The BEIR reports, besides reviewing the scientific literature on radiation health effects, develop quantitative cancer risk models for low-LET exposures as well as radon exposures. The United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) reports also review the literature on cancer and noncancer effects of radiation exposures. The committee developed quantitative cancer risk models and applied them to various populations. More recently, the International Agency for Research on Cancer (IARC), in its monograph series, evaluated cancer effects for various types of radiation exposures (IARC report 100D; IARC, 2009). This qualitative analysis determined that for each radiation type which cancer sites are considered to be causal. A brief summary was published after the meeting and the findings are reproduced here in Table 25-4 (El Ghissassi et al., 2009). We see from Table 25-4 that there are numerous Class 1 cancer sites for gamma-ray and x-ray, while only lung cancer is associated with radon exposures.

A-bomb Survivor Studies

The Radiation Effects Research Foundation (RERF) and its predecessor the Atomic Bomb Casualty Commission (ABCC) have reported a series of mortality studies on a fixed population (Life Span Study [LSS] cohort) of 120,321 individuals. These included A-bomb survivors and residents who were not present at the time of the bombing (NIC [not in city] 26,529). The most recent report is the 14th in the series and covers the years 1950 to 2003, and includes both cancer and noncancer mortality (Ozasa et al., 2012). There are also studies on cancer incidence, with the most recent for solid cancers during the period 1958 to 1998 and for hematopoietic

Table 25-4

IARC: Tumor Sites with Sufficient Evidence of Human Carcinogenicity

RADIATION TYPE	MAJOR STUDY POPULATIONS	TUMOR SITES (AND TYPES) ON WHICH SUFFICIENT EVIDENCE IS BASED
α-Particle and β-particle emitters		
Radon-222 and decay products	General population (residential exposure), underground miners	Lung
Radium-224 and decay products	Medical patients	Bone
Radium-226, radium-228, and decay products	Radium-dial painters	Bone, paranasal sinus, and mastoid process (radium-226 only)
Thorium-232 and decay products	Medical patients	Liver, extrahepatic bile ducts, gall bladder, and leukemia (excluding CLL)
Plutonium	Plutonium-production workers	Lung, liver, and bone
Phosphorus-32	Medical patients	Acute leukemia
Fission products, including strontium-90	General population, following nuclear reactor accident	Solid cancers and leukemia
Radioiodines, including iodine-131	Children and adolescents, following nuclear reactor accident	Thyroid
X radiation or gamma radiation	Atomic-bomb survivors, medical patients; in utero exposure (offspring of pregnant medical patients and of atomic-bomb survivors)	Salivary gland, esophagus, stomach, colon, lung, bone, skin (BCC), female breast, urinary bladder, brain and CNS, leukemia (excluding CLL), thyroid, kidney (atomic-bomb survivors, medical patients); multiple sites (in utero exposure)
Solar radiation	General population	Skin (BCC, SCC, and melanoma)
UV-emitting tanning devices	General population	Skin (melanoma) and eye (melanoma, particularly choroid and ciliary body)

Abbreviations: BCC, basal cell carcinoma; CLL, chronic lymphocytic leukemia; CNS, central nervous system; SCC, squamous cell carcinoma.

tumors during 1950 to 2001 (Preston et al., 2007; Hsu et al., 2013). RERF also publishes analyses of individuals in the Adult Health Study (AHS), which is a subcohort of LSS with 22,400 individuals and an additional 1000 in utero exposed. This subcohort is oversampled with more individuals who were exposed to the higher doses. Members of the AHS are given physical examinations every 2 years, and this provides much clinical data as well as biological samples. Details of the RERF study cohorts, publications, and databases can be accessed at the RERF Web site.

The LSS cohort's exposures are a whole-body exposure, which then allows for comparisons between specific cancer sites and their relative risks. The cohort is not likely to have many confounding issues because the basis of the dose estimation is the distance from the hypocenter. Finally the AHS subcohort allows for clinical, lifestyle, and biological measurements, which help to assure the lack of confounding and effect modifiers in the dose calculations. The problem with the cohort is that the results are extrapolated from a group of Japanese who survived the bombing and have different background cancer rates than other populations (e.g., Pierce et al., 2007).

The number of individuals in the LSS cohort is shown by city and colon dose (Gy) in Table 25-5 (adapted from Ozasa et al. [2012]). Although most individuals have low estimated doses, there is a good range of doses, with sufficient numbers at the higher doses

Table 25-5

Number of LSS Cohort Members by Colon Dose (Gy)

	TOTAL*	<0.005	0.005–	0.1–	0.2–	0.5–	1.0–	2.0–	UNKNOWN†	NIC‡	TOTAL§
Hiroshima	58,494	21,697	22,733	5037	5067	2373	1152	435	3442	20,179	82,214
Nagasaki	28,117	16,812	7228	937	1289	1051	611	189	3616	6350	38,107

**Total number of subjects with a reconstructed dose.*
†Those subjects with an unknown dose.
‡Not in the cities of Hiroshima or Nagasaki at the time of the bombing.
§Total of those with either a reconstructed dose, an unknown dose, or were NIC.

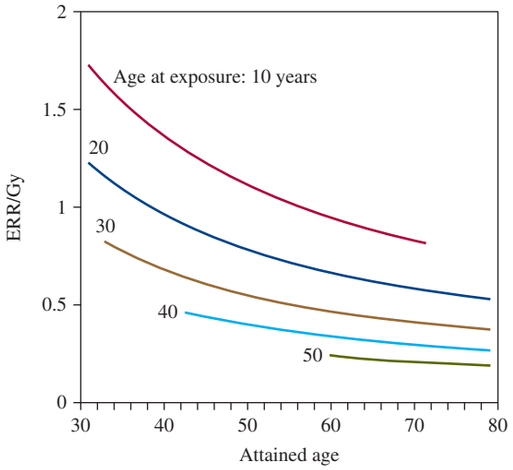

Figure 25-4. *LSS solid tumor mortality excess relative risk.*

for analysis and risk modeling. The individual dose reconstructions have evolved over the years with the current system completed in 2002 and referred to as DS02 (dosimetry system 2002). The uncertainty in the dosimetry is estimated to be about 30% and has been modeled for risk assessment purposes (see Pierce et al. [1990] and Little et al. [2008]).

The results of the mortality data show that for total solid cancers, the excess relative risk decreases with attained age and age at exposure. The modeled data are illustrated in Fig. 25-4, which is extracted from Ozasa et al. (2012). The excess relative risks for individual cancer sites and other causes of mortality are shown in Fig. 25-5, again from the Ozasa et al. (2012) analysis.

There have been sufficient incidence data so that both BEIR VII and UNSCEAR (2006) can model cancer incidence risk by cancer site. BEIR V previously used mortality data for their risk analyses. The most recent cancer incidence data for solid tumors, used by BEIR VII in its risk modeling, included the years 1958 to 1998, given in the publication by Preston et al. (2007). Each individual cancer site is analyzed and discussed in detail in the article by Preston. For total solid tumor incidence the estimated excess relative risk per Gy is 0.47 (0.40 to 0.54). Coincidently it is also 0.47 for solid tumor mortality study as shown in Fig. 25-5. Recently, the dosimetry at RERF has been revised (Cullings et al., 2017). One result of this change has been to add more curvature to the estimated dose–response function for solid cancer mortality.

Occupational Studies

Nuclear Worker Studies There have been numerous worker studies over the years among nuclear workers, primarily at governmental facilities. In most of these studies, mortality rates were compared with those in the general population. In most cases, the cancer mortality rates were less than those for the general public, which may be due to the healthy worker effect and differences between nuclear workers and the public. For those studies with external radiation dose estimates solid cancer risk estimates either increased or decreased with dose and had large confidence intervals (CIs; see BEIR VII for details). As an example in a nested case–control study of workers at the Portsmouth Naval Shipyard (PNS), 1097 lung cancer deaths were age-matched with 3291 controls among the cohort of 37,853 civilian workers (Yiin et al., 2007). After adjusting for confounders such as asbestos and welding fumes, lung cancer risk was associated with radiation exposure. However when work-related medical x-rays, which occur more frequently among radiation monitored workers, were included, lung cancer was no longer associated with radiation dose. The medical x-rays were of the same magnitude as the work exposures of the monitored workers. Because the individual covariates were associated with lung cancer risk, this study shows the importance of incorporating potential confounders in occupational radiation studies.

To address the problem of varied results, IARC carried out a joint analysis of seven nuclear facilities in Canada, the United Kingdom, and the United States, and is referred to as the three-country study (Cardis et al., 1995). This analysis involved a total of 95,673 workers and 3830 cancer deaths. The study estimated a slightly negative ERR per Sv of −0.9 (90% CI –0.4, 0.3) for total solid cancers, but observed a significant increase in mortality of both acute and chronic myelogenous leukemia. Also, multiple myeloma was significantly increased with increasing dose in the study. Although negative for total solid cancers, this result was not inconsistent with the risk estimates derived from the A-bomb studies.

The three-country study was followed by the 15-country study that involved a joint analysis of over 400,000 nuclear workers from 154 facilities (Cardis et al., 2007). As seen in Table 25-6 the number of workers and person-years at risk (pyr) are much greater in the 15-country study. However, the number of workers at the higher cumulative exposures is much lower. This is due to the elimination of workers in the 15-country cohorts who were monitored for internal exposures and also those who may have received an acute exposure of some significance. The study reported significant increases in smoking-related solid cancer mortality but not for leukemias, which was essentially the opposite of the three-country findings. There are a number of issues with the 15-country study as discussed in Dauer et al. (2010), namely, questions about the exclusion of workers included in the previous (three-country) study, such as the Idaho National Engineering Laboratory cohort, and exclusion of workers who were considered to have had potential for high internal dose. Also of concern is the inability to deal with smoking and the undue influence given to the results for one country, namely Canada, where risk estimates are very high and error-prone (Ashmore et al., 2010). The increase in overall solid cancer incidence would no longer be significant if the Canadian cohort were excluded; however, it would be consistent with risk estimates projected from the A-bomb studies.

Recently, a newer study of 308,297 nuclear workers in France, the United Kingdom, and the United States has been reported. This program is referred to as INWORKS (International Nuclear Workers Study) and has 8.2 million person-years of follow-up with 66,632 worker deaths. The excess relative risk (ERR) for solid cancer deaths was estimated to be 0.47 /Gy, which is the same as was observed in the LSS study. For this cohort it was reported that the estimated ERR for leukemia mortality was 2.96/Gy, which was primarily due to chronic myeloid leukemia (CML) (see Leuraud et al. [2015] and Richardson et al. [2015]). Risk estimates for the individual cancer sites are expected to be published in the near future. In an accompanying editorial, Little (2015) discussed the problems with using epidemiological data to estimating low-dose radiation risks.

A series of analyses of workers at the Russian nuclear facility at Mayak have been published. The Mayak workers generally experienced very high doses from both internal (plutonium, α particles) and external radiation exposures. Plutonium body burdens were based on urine analyses. Worker exposures of Pu239 and Pu240 and external exposures have been reassessed by Vasilenko et al. (2007).

Cause of death	ERR/Gy [*] (95%CI [†])	Cases

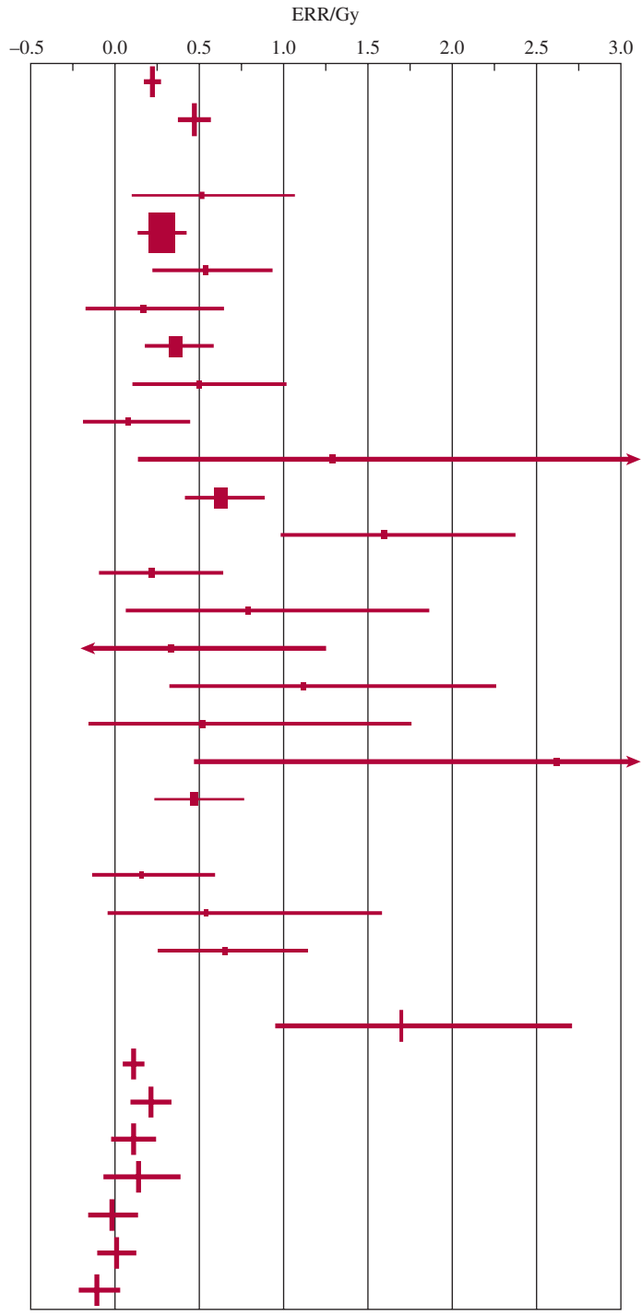

Figure 25-5. *LSS mortality 1950 to 2003: excess relative risk (ERR).* *ERR was estimated using the linear dose model, in which city, sex, age at exposure, and attained age were included in the background rates, but not allowing radiation effect modification by those factors. [†]Confidence interval. Horizontal bars show 95% confidence intervals. [‡]The size of plots for site-specific cancers was proportional to the number of cases. [§]ERR (95% CI) of leukemia was 3.1 (1.8, 4.3) at 1 Gy and 0.15 (–0.01, 0.31) at 0.1 Gy based on a linear quadratic model with 318 cases (not displayed in the figure). [‖]The lower limit of 95% CI was lower than zero, but not specified by calculation.

High levels of body burdens of plutonium greater than 7.4 kBq (mean 76 kBq) were found to have a relative risk of liver cancer of 17 (Gilbert et al., 2000) and 7.9 for bone cancer (Koshurnikova et al., 2000). Small nonsignificant increases were seen at low doses. These studies were based on the mortality experience of 11,000 workers. In a larger group of 21,000 workers 655 lung cancer deaths were evaluated (Gilbert et al., 2004). In contrast to the high-dose effects on the liver and bone, the effects of plutonium on lung cancer were found to be consistent with a linear dose–response. Recently, Sokolnikov et al. (2015) reported an ERR/Gy = 0.16 (0.07, 0.26) for solid cancer deaths other than those associated with plutonium exposures, namely liver, bone, and lung. Plutonium exposures to

Abbreviation: pyr, person-years at risk.

workers in the United States and the United Kingdom were much lower, and increase in cancer was not observed except possibly for a nonsignificant increase in lung cancer (Wilkinson et al., 1987; Wiggs et al., 1994; Omar et al., 1998). Also, experimental studies of plutonium administered to beagle dogs have predicted these high-dose effects in workers (e.g., Wilson et al., 2010). The dogs overpredicted the bone and liver cancer risks, but the lung cancers were similar.

Medical Radiation Workers It is estimated that there are 2.3 million medical radiation workers worldwide. Radiologists and radiological technologists have been studied epidemiologically for many years. These workers were some of the earliest exposed to radiation with the first finding in 1902 that radiation can cause skin cancer. It was recognized in the 1940s that radiologists had increased rates of leukemia (e.g., Ulrich, 1946). More recently, Yoshinaga et al. (2004) at the NCI reviewed cancer mortality from eight international cohorts involving 270,000 subjects. By far the greatest number of workers were from the study of 146,000 U.S. technologists (Mohan et al., 2003). In this study there were increases in breast cancer and non-chronic lymphocytic leukemias (non-CLLs), based on years worked for those employed before 1950 when exposures were much higher than today. The cohorts consistently show increases in leukemias for the early years with less consistency for skin cancer and breast cancer (Yoshinaga et al., 2004).

The U.S. Radiologic Technologists (USRT) health study is a large study (90,000 subjects with about 75% females), first contacted in 1983 to 1998, and is representative of the population of technologists with good employment history information and data on other risk factors such as smoking. Radiation monitoring (badges) was introduced in the 1950s and is beginning to be used in the analyses (Simon et al., 2006). Recently, Rajaraman et al. (2006) analyzed lung cancer in the cohort and did not find increases after adjustments for smoking. The USRT health study will continue with improved dosimetry and longer follow-up times. These studies will continue to be important because they involve low doses of continuous exposure in contrast to the acute exposure of the A-bomb survivors.

Chernobyl Cleanup Workers The Chernobyl cleanup workers are of interest because of their higher exposures compared with other nuclear workers. It has been estimated that there were 600,000 workers, with 240,000 of the workers exposed during 1986 to 1987 and having an average exposure of 100 mSv (Cardis et al., 2006). Ivanov et al. (2006) reported an analysis of 55,718 workers who had yearly physical examinations. The analysis covered two 5-year periods 1991 to 1995 and 1996 to 2001, with a total of 1370 cancer cases. The average dose for these workers during 1985 to 1986 was 130 mSv. Although there was an increase in the incidence of solid tumors, it was not significant. Cancer mortality was evaluated in a smaller cohort of workers (29,003 with 651 cancer deaths). The excess relative risk for solid tumors was significant (ERR = 1.52 per Gy) and the increase was observed in the highest dose interval (mean 200 mSv) with no increase in the lower-dose interval (mean 100 mSv). Besides solid tumors, a significant increase in leukemia incidence was observed for those with exposures greater than 0.15 Gy, compared with workers with lower exposures (Ivanov, 2007). Also, increases in the incidence of cardiovascular disease were observed among those at higher exposures.

A smaller cohort (10,332) of Chernobyl cleanup workers from the Baltic States was reported by Rahu et al. (2006). The mean exposure was 109 mGy, and 155 incidental cancer cases were observed. Although there were increases in thyroid (7 cases) and brain cancer (11 cases), they were not dose-related and were likely the result of close surveillance and multiple comparisons. More recently, Kashcheev et al. (2015) reported on 67,568 emergency workers' cancer incidence and mortality. The follow-up period was longer, from 1992 to 2009, resulting in 4002 solid cancer cases and 2442 cancer deaths. The estimated ERR/Gy for solid cancer incidence was 0.47, while for cancer mortality the ERR/Gy was 0.58 with both estimates being statistically significant.

Other than for leukemias, the follow-up period has been relatively short and it is thus too soon to conclude much about solid cancer risks. The relatively high reconstructed doses make it important to continue the follow-up of the cohorts and to evaluate the exposures and their uncertainties.

Nuclear Worker Registries The National Dose Registry of Canada includes 206,620 workers for the period 1951 to 1987. Ashmore et al. (1998) analyzed 5426 deaths and reported an increase in total cancer mortality among males (ERR = 3% per 10 mSv), which was marginally significant but not for any particular cancer, including leukemia. There was not a significant increase among females who comprised about half of the workers, but generally had much lower recorded doses. Sont et al. (2001) analyzed the Registry for cancer incidence of 191,333 workers for the period 1951 to 1988. Using national rates, the standardized incidence ratio (SIR) for all cancer was significantly less than 1 (SIR = 0.88 [90% CI 0.85, 0.92]). Leukemia was also significantly less than 1. When doses were used, the ERR for all cancer was 2.5 (90% CI 1.2, 4.0) and 5.4 (90% CI 0.2, 20.0) for leukemia. One difficulty with these analyses is that the cohort includes dental (0.3 mSv mean accumulative dose), medical (3.95 mSv), industrial (4.78 mSv), and nuclear workers (31.98 mSv), whose lifestyles may well differ as do their radiation exposures.

Muirhead et al. (2009) analyzed both mortality and incidence of the U.K. National Registry of Radiation Workers (124,723 workers). Total solid tumors were increased, ERR = 0.28 per Sv among 23,326 deaths and ERR = 0.27 among 11,165 malignant incident cases. Leukemias were also increased with ERR = 1.7 for mortality and 1.8 for incidence. Other than leukemia, individual cancer sites were not significantly increased. The increases for solid tumors and leukemias were significant using a 90% CI but not for a 95% CI.

Nonoccupationally Exposed Groups

Studies of the Techa River Exposures A joint U.S. and Russian program has been evaluating the health effects of those living near the Techa River. During the early 1950s radioactive waste from the Mayak nuclear production facility was released into the river. A dose reconstruction system has been developed (Degteva et al., 2000, 2007) and applied to a cohort of 30,000 people. Exposures were 55% internal from food and water, primarily of Cs 137 and Sr 89, 90. A mortality analysis based on 1842 solid cancer deaths resulted in an estimated ERR = 0.92 (0.2, 1.7) per Gy, and 6.5 (1.8, 24) based on 61 leukemia deaths (Krestinina et al., 2007). Cancer incidence for a subcohort of 17,000 individuals with 1836 cases reported an ERR = 1.0 per Gy with a mean cumulative exposure of 40 mGy stomach dose and mean bone marrow dose of 30 mGy. Recently, Davis et al. (2015) estimated the solid cancer incidence rate as ERR/Gy = 0.77 (0.13, 1.5). There are some uncertainties about the exposures in the early years, which may have been underestimated and, if increased, would reduce the risk estimates (Cardis, 2007).

High Natural Background Radiation Areas In 2000, a series of articles were published in a supplement issue of the *Journal of Radiation Research* that described the results of a joint China–Japan collaborative research program, which studied the population living in the high background radiation areas in Yangjiang, China. Cancer mortality was analyzed for the period 1979 to 1995 for 125,000 individuals, which accumulated 1.7 million person-years with 10,415 deaths including 1003 cancer deaths and a population average annual effective exposure of 6.4 mSv (Tao et al., 2000). Comparing individuals in the high background area to those in a control area, the relative risk was 0.99 (0.87, 1.14) for total cancer mortality. Dividing the high background area into low, medium, and high radiation exposures, the relative risks for nonleukemia cancer mortality actually decreased with dose (1.07, 0.98, and 0.91, respectively).

In an additional analysis, Sun et al. (2000) modeled the cancer risk using Poisson regression. The cumulative dose groups were in five 100-mSv intervals with the largest being 400+ mSv. The modeled solid tumor mortality risk did not increase with dose and was estimated to be negative but not significantly different from zero.

Recently Tao et al. (2012) analyzed cancer mortality (956 cases) among 31,604 people in the Yangjiang area between 1979 and 1998. The mean cumulative radiation dose was 84.8 mGy, with 21.6 mGy for those in the control area. The excess relative risk for solid cancers was ERR = –1.01 per Gy (95% CI –2.93, 0.95). Liver cancer is a major cancer that is negatively correlated with dose and is difficult to correctly diagnose. On removing the liver cancer from the analysis the ERR for solid cancers becomes 0.19 (–1.87, 3.04).

To evaluate the dose reconstruction, Jiang et al. (2000) calculated the correlation between estimated radiation exposure and frequency of dicentric and ring chromosomes, which are recognized as a good biomarker of radiation exposure. They observed that for those in the high radiation background area, the incidence of these markers agrees with what has been observed in other studies of radiation exposures and chromosome aberrations. This result provides some evidence in support of the program's exposure estimates. In conclusion, the high background Chinese studies have not shown an increase in cancer incidence at low dose and dose rate exposures.

The coastal area of Kerala, India, is a region of high natural radiation background that has been well studied. Nair et al. (2009) published an analysis of cancer incidence and individually determined gamma exposures in the region. A cohort of 70,000 individuals (age 30 to 84 years) were followed for 10.5 years, which resulted in 1379 cancer cases including 30 leukemias. The researchers also obtained individual data on smoking, education, occupation, and other possible cancer risk factors for their analysis. Cumulative dose intervals ranged from 0 to 49 mGy to 500+ mGy. For total cancers and for leukemia there were no increases observed among any of the dose intervals compared to the lowest dose interval. Excluding leukemia, the overall excess relative risk for cancer was estimated to be –0.13/Gy (95% CI –0.58, 0.46). Leukemia was not increased. The analysis included tobacco use and other risk factors that usually are not available in most other radiation epidemiological studies.

Although not a high background study, Kendall et al. (2012) studied childhood cancers in relation to natural background radiation in Great Britain. Using the National Registry of Childhood Tumours, the study involved over 27,000 cancer cases and matched controls with radiation exposures estimated on the basis of the mother's residence at time of birth. The mean cumulative dose from birth until diagnosis was 4 mSv. The study found a significant increase in leukemias with an estimated ERR of 12% (95% CI 3, 22) per mSv of gamma exposure to the red marrow. Other cancers were not significantly increased and radon was not a significant risk factor.

Semipalatinsk Fallout-Related Exposures The Semipalatinsk area of Kazakhstan has been studied for possible cancer effects resulting from radiation exposures from local fallout of the Soviet atomic nuclear weapons testing program. Bauer et al. (2005) studied six rural districts that had measurable levels of exposure and compared the individuals in the districts with six villages that were several hundred kilometers east of the nuclear test site. Follow-up of the populations began 5 to 10 years after the nuclear testing. Using soil samples taken in 1963 of strontium and cesium as well as information on the types of weapons, a dose reconstruction was developed for external and internal exposures. This dose reconstruction was based on the eight most dose-contributing nuclear tests.

For the purpose of analysis the approximate 10,000 individuals in the exposed area were matched with a group of 10,000 in the distant comparison area.

Cancer rates were considerably higher in the exposed groups of individuals, which resulted in significant dose–response relationships for most solid tumors. There appeared, however, to be an undefined bias in the distant control group since the rate ratios increased relatively little among the exposure categories. The authors' estimate for total solid tumors was ERR/Sv = 0.81 (0.46, 1.33), which is similar to the A-bomb cancer risk estimates. The CIs are fairly narrow but the uncertainty in the dose reconstruction was not included in the analysis. The lack of a dose–response is possibly explained by the fact that the study was ecological in nature.

Other Nonoccupational Studies

Buildings with Cobalt 60 A group of 7271 individuals who resided in buildings with high levels of Cobalt 60–contaminated steel in Taiwan have been studied by Hwang et al. (2006). The average cumulative exposure was about 50 mSv, and after a follow-up

period of 16 years, a total of 141 cancer cases were identified. For total solid cancers (82 cases) compared to the national rates, the total cancers were less than expected, but thyroid cancer (7 cases) and non-Hodgkin lymphoma (5 cases) were significantly increased. This is a small study that shows little effect of continuous exposure. It is also difficult to interpret because the exposed population was likely of a higher social economic status (SES) than the general comparison population.

More recently, Hwang et al. (2008) reported significant increases in leukemia excluding CLL, and marginally significant increases in breast cancer. This was based on a dose–response analysis using an exposure assessment system developed to reconstruct the doses to the individuals. The average cumulative dose was 48 mGy.

Populations Residing Near Nuclear Facilities Ecological cancer studies have been carried out in the vicinity of nuclear power plants in many countries. There has often been reported an unexplained increase in childhood leukemia (Laurier et al., 2002; Baker and Hoel, 2007). Spix et al. (2008) and Kaatsch et al. (2008) conducted a childhood cancer case–control study in the areas in the vicinity of 16 German nuclear power plants. They observed 1592 cancer cases with 593 cases of leukemia among children under the age of five during the period 1983 to 2003. Children within 5 km of a nuclear facility had a significant increase in leukemias, but not for other cancers (37 leukemia cases and 54 controls). It was not possible to measure for possible confounders. The authors stated that radiation exposures near these German nuclear power plants are less than the natural background radiation by a factor of 1000 to 100,000.

In France a study of childhood leukemia among children living in the vicinity of the 29 French nuclear sites reported 670 cases, with 729 cases expected from national rates (White-Koning et al., 2004). They observed no trend in leukemia rates with respect to distance. For those within 5 km of a facility, there were 65 leukemia cases, with 75 expected, and for children less than 5 years of age, there were 39 leukemia cases with 40 cases expected.

Evrard et al. (2006) analyzed childhood leukemia, which included three additional years of follow-up from the White-Koning study. Instead of the usual distance surrogate for dose, the researchers estimated doses to the bone marrow based upon the nuclear plants' radioactive discharges. The Institute for Radiation Protection and Nuclear Safety combined the radionuclide discharge data and the local climate data to model the environmental exposure levels. Estimated doses to the red marrow for those in the vicinity of the nuclear sites ranged from 0.06 to 1.33 μSv per year. There were a total of 750 leukemia cases (age less than 15 years) with 795 expected and 394 among those less than 5 years of age (415 expected). There was no trend of leukemia incidence based on yearly exposure rates. The authors concurred with the authors of the German study by estimating that the doses due to releases in the vicinity of the nuclear facilities are approximately 1000 to 100,000 times lower than the average dose due to natural radiation sources.

The recent COMARE (2011) report, focused on leukemias in children around nuclear power plants. The report discusses in detail the German studies as well as studies in other countries. Importantly Kinlen (1988, 2011) describes the concept of population mixing, which basically is the idea that workers arriving in a typically rural area bring foreign infectious agents that in turn will affect local childhood leukemias. In his article Kinlen (2011) focuses on the nuclear power plant studies and the German results in particular. The Kinlen hypothesis of population mixing has been discussed by some authors to explain increased leukemia effects in children when there is no evidence of radiation exposures from the nuclear plants.

The National Research Council (2012) released a review of studies around nuclear facilities with recommendations on how a study could be carried out in the United States using cancer registry data. Previously the NCI (Jablon et al., 1991) analyzed cancer mortality rates in those counties with nuclear power reactors compared with control counties. Basically no differences were found; however, the use of counties as the analysis unit is likely to be too great a geographical area to detect any possible small effects.

Radionuclides

Radon There have been some human studies involving exposures to radionuclides but the data are limited other than for radon, which has been extensively studied. Radon is a natural radioactive gas produced by the decay of uranium and thorium. Originally, exposures to radon and its daughter radionuclides among uranium miners and some other groups of miners established that high exposures were a clear risk for lung cancer. Cancer causation has been restricted to lung cancer but there are also some suggestions that leukemia risk may also be an issue (see the BEIR VI [1999] and IARC [2009] reports). More recently there have been many case–control studies in the United States and Europe of lung cancer and radon exposure in the home. These studies have been brought together for joint analyses of those studies carried out in Europe (13 studies; Darby et al., 2006) and for those studies from North America (7 studies; Krewski et al., 2006). The analysis by Darby, as well as Krewski, observed the data to be best fit by a linear function in dose, with Darby estimating the excess relative risk of lung cancer to be 0.08 per 100 Bq/m^3 and 0.10 in the Krewski analysis. The lung cancer risk was also significantly increased when the cases were restricted to exposures less than 200 Bq/m^3. The lung cancer effects were also consistent, with the risks projected downward from the higher exposed uranium miners, that is, 0.12 per 100 Bq/m^3. When Darby adjusted the data for uncertainties in the radon exposure estimates, the excess relative risk increased to 0.16. BEIR IV, which also includes chapters on radionuclides other than radon, provides tables giving the excess lifetime relative risk for various ages at first exposure, exposure level, and period of exposure. This is done for both males and females and for smokers and never smokers. These tables were not included in the newer BEIR VI report on radon; however, Chen (2005) published similar tables using the newer BEIR VI risk models. Currently (e.g., Darby et al., 2006), the risk analyses find that the relative risk for lung cancer and radon exposure is independent of smoking status. Average radon levels in the home for various countries are given in the *WHO Handbook on Indoor Radon 2009* and it is estimated that 3% to 16% of lung cancers are attributable to radon in the home depending on the risk model used. From Table 25-7 we see that for the United States, with an average level of 46 Bq/m^3, and using BEIR VI risk models, the attributable lung cancer risk is 10% to 14%.

Radium There are 25 isotopes of radium of which 4 occur naturally (radium 223, 224, 226, and 228); the others are man-made or decay products of man-made radionuclides. Radium 226 with a half-life of 1601 years is by far the common natural form, followed by 228 with a half-life of 5.75 years. Radium 223 and 224 have half-lives of only a few days. Except for radium 228, which is a β emitter, the other three are all α emitters. The different isotopes have been used both occupationally as luminescent paint on watches and instruments (radium 226 and 228) and in medical applications (radium 223 and 224). These uses, as well as radium found environmentally in drinking water, have provided material for many

epidemiological studies. Beginning in the 1920s, young women worked painting the dials of watches with paint containing radium 226 and 228. Many of them "pointed" the tips of their paintbrushes by mouth resulting in ingestion of relatively large amounts of radium for some of the women. A cohort of 1476 of these dial painters has been established with careful exposure reconstruction (Rowland et al., 1978). Radium as a bone seeker resulted in increases in bone cancer as well as paranasal sinus cancers. Although about one-half of the cohort had cumulative exposures less than 1 Gy, there were no bone cancers for those who were exposed to less than 10 Gy, which using a quality factor of 20 for α irradiation gives 200 Sv. In a statistical modeling of the bone cancers, it was estimated that 5 Gy was a threshold level (Hoel and Carnes, 2004). During the 1940s instrument dials were painted in Britain without the tipping of brushes by mouth (Baverstock and Papworth, 1989). In a follow-up of this cohort, cancers and bone cancers in particular were not increased.

Bone sarcomas were also the major cancer effect among patients with tuberculosis and ankylosing spondylitis who were treated with high doses of radium 224 (mean bone surface dose of 30 Gy) in two cohort studies in Germany (Wick et al., 1999; Nekolla et al., 2010). There were increases in bone cancer in both studies, but there were also some increases in other cancer sites (Nekolla et al., 2010).

Plutonium Plutonium is used for nuclear weapons production, and in the production of mixed oxide fuels. Most of the exposure to plutonium is to workers involved in the processing of plutonium in nuclear weapons (Pu 239) and in nuclear power generation (Pu 238). Several groups of workers exposed to plutonium have been studied in the United States, the United Kingdom, and Russia. The major exposure to plutonium is by inhalation and is retained primarily in the lung, liver, and bone, and has been studied in the United States, the United Kingdom, and Russia. The most informative studies are those of workers employed at the Russian Mayak plant where exposures to plutonium were substantial. Dose–response relationships have been shown for cancers of the lung, liver, and bone over a wide range of doses (see Gilbert et al., 2000, 2004; Koshurnikova et al., 2000; Sokolnikov et al., 2008). Internal estimated plutonium doses were very high: up to 5+ Gy for the lung, 23 Gy for the liver, and 144 Gy for the bone surface.

Radioiodine Releases from nuclear facilities of fission-product radionuclides deposited in the environment as well as internal doses from the ingestion of foods containing fission products have been the result of the Chernobyl and Fukushima accidents. Cesium 134 and 137 as well as Iodine 131 were the most important radionuclide exposures that potentially are health risks. Besides nuclear accidents, there are studies of the health effects from exposures to nuclear testing fallout from the Nevada test site and the testing in the South Pacific. The major observable health effect has been childhood thyroid cancer resulting from the β emitter Iodine 131, which has a half-life of only 8 days. From studies of external radiation exposures in the A-bomb survivor studies as well as the children who were treated by radiation for tinea capitis (ring worm present on the scalp), it is clear that radiation is a risk for thyroid cancer for exposures to adolescents. Ron et al. (1995), in a pooled analysis of the studies of external exposures, observed for childhood exposures that the excess relative risk per Gy was 7.7 (95% CI 2.1, 28.7). Iodine 131 is of particular concern because it is taken up by the thyroid gland. Cardis et al. (2005) studied 276 case patients with thyroid cancer and 1300 controls, ages less than 15 years at the time of the Chernobyl accident. Individual doses were estimated for each subject based on their location and diets at the time of the accident. A dose–response relationship was observed between Iodine 131 dose to the thyroid received in childhood and thyroid cancer risk. For a dose of 1 Gy, the estimated odds ratio (OR) of thyroid cancer ranged from 5.5 to 8.4 depending on the risk model. The risk of radiation-related thyroid cancer was three times higher in iodine-deficient areas and the use of potassium iodide as a supplement reduced this risk of radiation-related thyroid cancer by a factor of 3. Cardis et al. (2006) further predict that within Europe by 2065 about 16,000 cases of thyroid cancer and 25,000 cases of other cancers may be expected due to radiation from the accident, whereas several hundred million cancer cases are expected from other causes. Ron (2007) estimated that 90% of the thyroid cancer was due to the ingestion of iodine 131.

NONCANCER EPIDEMIOLOGY

Cardiovascular Disease

Fig. 25-5 shows that there are mortality effects of radiation exposure in the A-bomb studies besides cancer. What is of particular interest is cardiovascular disease (CVD) mortality, because although it may have a lower relative risk from radiation exposure than solid tumors, it accounts for more total background deaths. Atherosclerosis is an inflammatory disease of the arteries, which can lead to ischemia of the heart. In a study of inflammatory biomarkers (TNF-α, IL-10, IgM, IgA, and IFN-γ) as well as erythrocyte sedimentations rates among A-bomb survivors, it was shown that these markers were associated with radiation exposure. It has been estimated that an exposure of 1 Sv was equivalent to an increase in immunological age of 9 to 10 years (see Hoel [2006] for a discussion). The LSS data show a linear dose–response for heart disease mortality but curvilinear for stroke mortality (Shimizu et al., 2010; Takahashi et al., 2017). It is not clear whether there are effects at acute exposures below 0.5 Gy. A current review of what we scientifically understand about CVD and radiation can be found in Darby et al. (2010), and a meta-analysis of the epidemiological studies in Little et al. (2012).

Cataracts

Cataracts were one of the earliest radiation-associated effects found after the discovery of x-rays. It has long been believed that it results from only high doses of radiation to the lens of the eye. For example, the ICRP estimates that acute exposures of 0.5 to 2 Sv are required to cause detectable lens opacities and 5 Sv for vision-impairing cataracts. For protracted exposures, they estimate the dose thresholds as 5 and 8 Sv. There are basically three types of cataracts that are described by Asbell et al. (2005). These types are nuclear or nuclear sclerosis, cortical, and posterior-subcapsular (PS) cataracts. Each of these clinical types has its known risk factors such as cigarette smoking for nuclear and possibly PS cataracts, while UV-B is a risk factor for cortical cataracts. Ionizing radiation is a risk factor for both cortical and PS cataracts but not nuclear sclerotic cataracts (Rafnsson et al., 2005; Worgul et al., 2007). Recent studies have, however, suggested that radiation exposures to the lens confer the risk of opacities at doses well under 1 Sv. The most carefully studied population for relating ionizing radiation and cataracts is the A-bomb survivors. In an ophthalmological screen of members of the adult heath study, the researchers found a statistically significant dose response for PS opacities OR = 1.41 (threshold 0.7 Gy) and for cortical opacities OR = 1.29 (threshold 0.6 Gy). A greater risk for PSC opacities was observed for those exposed at a younger age. In a subsequent study of survivors who had lens removal surgery the radiation risk was estimated to be OR = 1.39 with a low estimated threshold of 0.1 Gy (10 rem). There was no evidence of an association of nuclear cataracts with radiation exposure.

Shore et al. (2010) have shown that among Japanese A-bomb survivors, the risks for cataracts requiring lens surgery are at doses under 1 Gy. The CI on the dose threshold for cataract surgery indicated that the data are consistent with a dose threshold ranging from 0 to 0.8 Gy. What is not known is what are the risks at continuous or protracted exposures. Also there is limited evidence that those exposed at a younger age are at greater risk. The question of thresholds of effect continues to be undecided, with no consensus at this point in time. Classically, PSC opacities were considered to be the risk of ionizing radiation exposure to the lens. Several studies have also found that radiation affects cortical opacities. As far as the degree of risk is concerned, the typical estimate from the studies suggests that 1 Gy of exposure to the lens would correspond to a relative risk of about 1.4 for PSC and somewhat less for cortical opacities. For a general discussion of the scientific issues see Blakely et al. (2010). Also, the NCRP (2017) has completed a committee review of the risks as well as the possible mechanisms. The report is summarized in the published article by Dauer et al. (2017).

Mental Effects

In the A-bomb survivor analyses, significant effects on the developing brain were observed among those exposed during the period of the 8th week through 25th week of gestation. During the most sensitive period of 8 to 15 weeks, there was an increased frequency of severe mental retardation, a diminution in IQ scores and school performances, as well as an increase in the occurrence of seizures. During this sensitive period there is a rapid increase in the number of neurons; they migrate to the cerebral cortex where they lose their capacity to divide, becoming perennial cells. Of the 30 cases of severe retardation, 60% had small head sizes and of those with small head sizes about 10% were retarded. Also the highest IQ score among the 30 cases was 64. For retardation, the dose–response appears linear with an estimated threshold at about 0.2 Gy. At about 1 Gy the statistical regression estimates about 50% retardation. The data also suggest that at 1 Gy there is a loss of 25 to 31 IQ points with no observed effect below 0.1 Gy (Otake et al., 1990, 1991; also see COMARE, 2004).

DISCUSSION

The major issue in radiation health effects is the causation of cancer. We now see noncancer effects such as CVD at low-dose and also low dose-rate exposures that occur at environmental levels and in diagnostic medical screening. Currently, the LNT model is used to estimate these effects well below what can be observed in epidemiological studies. The simple defense of the LNT model is that the physical energy deposition of ionizing radiation increases cancer risk linearly with increasing dose, and the carcinogenic effectiveness is constant independent of dose. The French National Academy of Sciences and the French National Academy of Medicine (Tubiana et al., 2005) have taken an opposing view on the appropriateness of the use of the LNT model. It is generally agreed that epidemiological studies have been unable to detect increases in cancer below exposures of 100 mSv. The French Academy's reason for believing that thresholds may be present and that the LNT overestimates risk is based on radiobiology. It is recognized that a cell is not passively affected by the accumulation of lesions induced by ionizing radiation. The cell reacts through at least three main mechanisms: first by reacting against radiation-induced ROS; second by eliminating damaged cells by either apoptosis or through cell death during mitosis of unrepaired cells; and third by immunosurveillance systems that eliminate clones of transformed cells. The Academy states that experimental data strongly suggest that a practical threshold exists, but the current data do not indicate at what dose or dose rate of radiation it becomes trivial, probably somewhere between 10 and 50 mGy (Tubiana, 2005). For a recent debate see Brenner (2009) and Averbeck (2009). The BEIR VII committee concluded:

The committee judged that the linear no-threshold model (LNT) provided the most reasonable description of the relation between low-dose exposure to ionizing radiation and the incidence of solid cancers that are induced by ionizing radiation.

The answer awaits further progress in radiobiology.

A second question is whether there is a dose and dose-rate effectiveness factor (DDREF) greater than 1. In other words, are chronic exposures less of a cancer risk than an acute exposure such as from the A-bomb studies that provide the quantitative risk estimates? Previously a value of 2 had been used until BEIR VII concluded that it should be 1.5. Recently it has been argued that it should probably be equal to 1 (Jacob et al., 2009). Animal studies have generally suggested that a DDREF is appropriately between 2 and 10 (BEIR V); however, these studies were generally conducted at relatively high doses.

For a much more in-depth reading of health effects of ionizing radiation the reader is referred to two outstanding text books by Hall and Giaccia (2005) and Mettler and Upton (2008). For an understanding of radiation exposures there are several available health physics texts (e.g., Cember and Johnson, 2009). Finally, BEIR VII is a very good source of the current scientific understanding of biology, toxicology, and epidemiology of radiation exposures. Further committee conclusions about health effects can be found in IARC (2009) and UNSCEAR (2006).

INTRODUCTION

The earliest humans have used plant extracts and animal venoms for hunting, war, assassination, and political intrigue for millennia. The Ebers Papyrus, which dates to around 1550 BC, describes concoctions using plant substances as primary ingredients. The toxic properties of plants and animals often enhance their ability to survive in their surroundings and against predators. Some toxic compounds are used primarily to aid an animal in obtaining food, whereas plants have developed toxic properties to specifically ward off being used as food. These toxic compounds are invaluable as tools and in the insight that they provide into the systems that they disrupt and poison. One major complication to the study of plant and animal poisons arises from their complexity as mixtures. Studies readily separate and evaluate individual components, but it is very difficult to use purified components to make the original toxin or venom. Nevertheless, extensive study of many toxins has contributed to a greater understanding of their biology and chemistry. Toxins have been utilized as tools to study human biochemistry and physiology in order to pave the way for new pharmaceuticals. Clinical evaluation of human poisoning is complicated by questionable identification of plant or animal species and the inability to quantify the level of exposure. In this chapter, an overview of specific plant and animal toxins and their effects will precede a

short discussion of the considerable effort to harness the natural pharmacopeia for clinical use.

INTRODUCTION TO PLANT TOXICITIES

The plant kingdom contains potentially 300,000 species, and the toxic effects of plants serve primarily as defense mechanisms against natural predators. Toxicity in humans can result from simply touching as well as ingesting plants to cause a truly wide array of deleterious effects. Toxic effects on humans can range from simple hay fever caused by exposure to plant pollen all the way to serious systemic reactions caused by ingestion of specific plants. Table 26-1 lists some of the poisoning syndromes that plants can produce (Nelson et al., 2007).

Many variables can affect the concentration of a plant's toxin and can be a major factor in the severity of reaction one will experience on exposure. These factors include what part of the plant exposure is from, the age of the plant, amount of sunlight and soil quality that the plant has grown in, and genetic differences within a species. Also, plant toxins fall under a number of different chemical structures, which is useful in understanding related toxins. Table 26-2 lists some of the common classifications.

The number and variety of plants that have some level of use or toxicity are far too many to be discussed here (see Table 1 in Polito et al. [2016]). Criteria for inclusion for discussion are based on how frequently human exposure occurs, the seriousness of these exposures, and also how well the toxic agent is scientifically understood. Excellent source material can be found in the comprehensive texts by Barceloux (2008), Dart (2004), Cameron et al. (2015), Leikin and Paloucek (2008), and Nelson et al. (2007).

TOXIC EFFECTS BY ORGAN

Skin

Irritant Contact Dermatitis Plants causing irritation of the skin on contact are rather common (Nelson et al., 2007). A list of such plants containing their family, genus, and common names can be found in Table 26-3. The trichomes, or barb-like hairs (Fig. 26-1), found on stinging nettles (*Urtica* species, Urticaceae) puncture skin on contact and release an irritating sap containing a mixture of formic acid, histamine, acetylcholine, and serotonin (Kavalali, 2003). Various species of *Urtica* can be found all over the world; however, the most dangerous is *U. ferox* (poisonous tree nettle), which is most common in New Zealand. Exposure has been reported to cause death in humans and animals. *Mucuna pruriens* (cowhage), which also deploys its toxin via barbed trichomes on contact, may cause pain, itching, erythema, and vesication. Mucinain, contained

Table 26-1

Poisoning Syndromes Caused by Plants

SYNDROME	GENERA	MECHANISM(S)
Antimuscarinic	*Atropa, Datura, Hyoscyanmus, Solanum*	Blockade of muscarinic cholinoceptors
Cardiotoxic	*Adenium, Digitalis, Convallaria, Nerium*	Inhibition of cellular Na^+, K^+-ATPase increases contractility, enhanced vagal effect
Convulsants	*Anemone, Conium, Labrunum, Nicotinia, Ranunculus*	Blockade of gamma-aminobutyric acid (GABA) receptor on the neuronal chloride channel, alteration of acetylcholine homeostasis, mimic excitatory amino acids, sodium channel alteration, hypoglycemia
Cyanogenic	*Eriobotrya, Hydrangea, Prunus*	Gastric acid hydrolysis of cyanogenic glycosides releases cyanide
Dysrhythmia	*Acotinum, Rhododendron, Veratrum*	Sodium channel activation
Nicotinic	*Conium, Laburnum, Lobelia, Nicotinia*	Stimulation of nicotinic cholinoceptors
Pyrrolizidine	*Crotalaria, Heliotropium, Senecia*	Pyrroles injure endothelium of hepatic or pulmonary vasculature leading to veno-occlusive disease and hepatic necrosis
Toxalbumin	*Abrus, Ricinus*	Protein synthesis inhibitors leading to multiple organ system failure

Table 26-2

Chemical Classification of Plant Toxins

CHEMICAL CATEGORY	GENERA	EXAMPLES
Alkaloids	*Atropa, Senecio, Nicotinia, Coffea, Papaver, Solanum, Acotinum*	Tropines, pyrrolizidines, pyridines, purines, isoquinolines, steroids, diterpines
Glycosides	*Digitalis, Aesculus*	Steroids, coumarins
Proteinaceous compounds	*Abrus, Amanitin, Lathyrus*	Toxalbumins (abrin, ricin), polypeptides (amatoxins, phallotoxins, phalloidin), amines (aminopropionitrile)
Organic acids	*Caladium, Dieffenbachia, Rheum*	Oxalates
Alcohols	*Cicuta, Eupatorium*	Cicutoxin, tremetol
Resins and resinoids	*Cannabis, Rhus*	Tetrahydrocannabinol, urushiol

Table 26-3

Selective Plants Producing Contact Dermatitis

BOTANICAL FAMILY	GENUS SPECIES	COMMON NAME
Amaryllidaceae	*Narcissus*	Narcissus
Apocynaceae	*Nerium oleander*	Oleander
Bromeliaceae	*Ananas comosus*	Pineapple
Asteraceae	*Ambrosia, Aster, Chrysanthemum, Rudbeckia hirta, Tagetes minuta*	Ragweed, aster, chrysanthemum, black-eyed Susan, Mexican marigold
Euphorbiaceae	*Ricinus communis*	Castor bean
Fumariaceae	*Dicentra spectabilis*	Bleeding heart
Ginkgoaceae	*Ginkgo biloba*	Ginkgo
Liliaceae	*Allium cepa*	Onion
Myrtaceae	*Eucalyptus globulus*	Eucalyptus
Pinaceae	*Abies balsamea*	Balsam fir
Saxifragaceae	*Hydrangea*	Hydrangea
Solanaceae	*Lycopersicon esculentum, Solanum carolinense, S. turerosum*	Tomato, horse nettle, potato
Umbelliferae	*Daucus carota, Heracleum lanatum*	Carrot, cow parsnip
Urticaceae	*Urtica dioica, U. urens*	Stinging nettle

Figure 26-1. *Stinging hairs of Urtica ferox (nettles).*

in the toxin, is the proteinase responsible for causing the pruritus (Southcott and Haegi, 1992).

Certain species of *Ranunculus* (buttercup) contain a compound known as ranunculin, which is enzymatically broken down into the toxin protoanemonin. On contact with skin, protoanemonin found in *Anemone* (buttercup) is converted to anemonin, which is the

Figure 26-2. *Euphorbia pulcherrima (poinsettia).*

irritant directly responsible for the resulting dermatitis. If ingested, protoanemonin may cause severe irritation of the gastrointestinal tract (Kelch et al., 1992).

Damage to the stems or leaves of the genus *Euphorbia* (Euphorbiaceae, spurge family) causes exudation of a milky latex that contains diterpene esters that are irritating to the skin. *Euphorbia marginata* (snow-on-the-mountain) is a common plant in the United States that is used in flower arrangements by florists. Dermal contact with its latex can cause skin irritation (Urushibata and Kase, 1991). In addition, serious eye irritation has been reported (Frohn et al., 1993). The poinsettia (*Euphorbia pulcherrima*; Fig. 26-2), which is ubiquitous at holiday times, may cause contact dermatitis (Massermanian, 1998).

Allergic Contact Dermatitis Many people have experienced allergic dermatitis (see Chap. 19, "Toxic Responses of the Skin"), most frequently from contact with poison ivy. Allergic dermatitis is an actual allergic reaction occurring within the skin as opposed to just a response to the presence of an irritant. Due to this immunological component, the severity of the reaction can range widely.

Philodendron scandens (Araceae, arum family) and the toxicodendron group of plants, which contains *Rhus radicans* (poison ivy; Fig. 26-3), *Rhus diversiloba* (poison oak), and *Rhus vernix* (poison sumac), are all known to cause allergic dermatitis. *P. scandens* is a common houseplant that produces allergenic resorcinols, especially 5-*n*-heptadecatrienyl resorcinol (Knight, 1991). In the *Rhus* species, the allergen is a fat-soluble substance called urushiol that can penetrate the stratum corneum and then bind Langerhans cells in the epidermis. These haptenated cells then migrate to lymph nodes, where T cells are activated resulting in the allergic response (Kalish and Johnson, 1990). Ingestion of *Rhus* species has been reported to cause generalized dermatitis (Oh et al., 2003). Sap of the mango fruit (*Magnifera indica*, Anacardiaceae) can also cause allergic dermatitis due to the presence of oleoresins that, with repeated exposure, will cross-react with allergens of poison ivy (Tucker and Swan, 1998).

Figure 26-3. *Toxicodendron radicans (poison ivy).*

Alkaloids present in the sap of daffodils, hyacinths, and tulips can sometimes cause irritation. Irritation can also be caused by contact with needle-like crystals of calcium oxalate, also known as raphides, which are present on these plants' bulbs (Gude et al., 1988). The major culprit is the compound tulipalin-A, which causes "tulip fingers" from handling tulip bulbs (Christensen and Kristiansen, 1999). Tulipalin-A can be found in concentrations up to 2%. A safe threshold for this allergen is considered to be 0.01% (Hausen et al., 1983). Table 26-4 contains more plants that cause irritation due to oxalates.

"Latex-fruit syndrome" is the result of cross-sensitivity to latex in rubber gloves and some fruits. *Hevea brasiliensis* (the latex tree) produces prohevein, a chitin-binding polypeptide that is also found in several plants. Hevein, a 43 amino acid N-terminal fragment of prohevein, is the major binding component (Kolarich et al., 2005). Individuals who are allergic to rubber latex may become sensitized to fruits containing a chitinase with a hevein-like domain, such as banana, kiwi, tomato, and avocado (Blanco et al., 1999).

Lichens, such as species of *Usnea* and *Cladonia*, are known to cause dermatitis due to the production of usnic acid (a benzofuran) and related acids (Aalto-Korte et al., 2005). Usnic acid has also been implicated in hepatotoxicity following use of certain nonprescription weight loss supplements (Han et al., 2004).

Photosensitivity Dermatitis does not necessarily have to be caused by skin contact. Consumption of *Hypericum perforatum* (St. John's wort) by animals can lead to serious dermatitis and even may be life threatening. The toxic agent is hypericin (a bianthraquinone) that once ingested and dispersed systemically causes photosensitization of the animal's skin. On exposure to sunlight, edematous lesions form on areas of skin that are not protected by hair such as the nose and ears (Sako et al., 1993). Photosensitization caused by St. John's wort in humans is a rare occurrence; however, an increased response to therapeutic exposure to ultraviolet therapy has been reported (Beattie et al., 2005). However, compounds in *Hypericum perforatum* cause induction of cytochrome P450s, leading to potential interactions with many drugs (Russo et al., 2014).

Respiratory Tract

Allergic Rhinitis Rhinitis from inhalation of plant pollens is a seasonal problem for many individuals. A chromosomal association in these individuals is under investigation (Blumenthal et al., 2006). Trees, grasses, and weeds are all responsible to contributing to airborne pollen. Grass species *Poa* and *Festuca* are major contributors along with pollen from several weed genera in the Asteraceae (e.g., mugwort, *Artemisia vulgaris*, in Europe, and ragweed, *Ambrosia* sp., in North America; Fig. 26-4). The common denominator in the various pollen allergens is the conserved binding domain known as profiling, which is also found in birch pollen (Hirschwehr et al., 1998). Asthma and rhinitis have been linked to individuals who are exposed to cascara sagrada (*Rhamnus purshiana*) (Giavina-Bianchi et al., 1997), or workers in greenhouses in which bell peppers are growing (Groenewoud et al., 2006).

Table 26-4

Selective Plants Causing Gastrointestinal Irritation Due to Release of Raphides of Oxalates

BOTANICAL FAMILY	SCIENTIFIC NAME	COMMON NAME
Amaranthaceae	*Halogeton glomeratus*	Saltlover, halogeton
Araceae	*Alocasia macrorrhiza*	Giant taro
	Anthurium andreanum	Flamingo Lily
	Caladium bicolor	Caladium
	Dieffenbachia sp.	Dumbcane
	Epipremnum sp.	Pothos, Devil's Ivy
	Monstera sp.	Shingle plant, Swiss Cheese plant
	Philodendron scandens	Philodendron
	Scindapsus aureus, Pothosaureus sp.	Marble queen
	Spathiphyllum sp.	Peace Lily
	Syngonium podophyllum	Arrowhead plant
Chenopodiaceae	*Spinacia oleracea*	Spinach
Commelinaceae	*Tradescantieae* sp.	Spiderworts
Onagraceae	*Fushsia* sp.	Fuchsia
Oxalidaceae	*Oxalis* sp.	Wood sorrel
Palmae	*Caryotamitis* sp.	Fishtail palm
Polygonaceae	*Rheum rhaponticum*	Rhubarb
Portulacaceae	*Portulaca* sp.	Purslane
Vitaceae	*Parthenocissus quinquefolia*	Virginia creeper
	Parthenocissus triscupidata	Boston ivy, Japanese creeper

Cough Reflex Workers who process peppers have a significantly increased incidence of coughing when specifically handling *Capsicum annuum* (sweet pepper) and *Capsicum frutescens* (red pepper). These two types of peppers produce the major irritants capsaicin (*trans*-8-methyl-*N*-vanillyl-6-nonenamide) and dihydrocapsaicin (Surh et al., 1998). Specific nerves in the airway have been found to be capsaicin-sensitive, which leads to the irritation and cough (Blanc et al., 1991).

Toxin-Associated Pneumonia The pneumotoxin, 4-ipomeanol, is produced in sweet potato roots (*Ipomea batatas*, Convolvulaceae) by the mold *Fusarium solani*. 4-Ipomeanol is activated by human

Figure 26-4. *Ambrosia psilostachya (western ragweed).*

cytochrome P450s to an intermediate that binds to DNA (Alvarez-Diez and Zheng, 2004). In cattle and rabbits, the major P450 activator is CYP4B1 found in the lung that results in pneumonia. In the mouse, CYP4B1 is most abundant in the kidneys that results in renal toxicity, and in humans multiple subsets of liver P450 enzymes are responsible for activating 4-ipomeanol (Baer et al., 2005).

Gastrointestinal System

Direct Irritant Effects Ingestion of a toxic plant can cause irritation of the gastrointestinal tract, often resulting in nausea, vomiting, and diarrhea. Many different compounds produced by plants can cause mild to severe versions of these effects. A list of plants known to cause these effects is provided in Table 26-5. Ingestion of ripe tung nuts (*Aleurites fordii*) causes abdominal pain, vomiting, and diarrhea. Outbreaks of poisoning are most likely to occur in children (Lin et al., 1996).

Toxic quinolizidine alkaloids are found in buffalo beans, also known as buffalo peas (*Thermopsis rhombifolia*), which grow naturally in the western United States. Ingestion by children causes nausea, vomiting, dizziness, and abdominal discomfort (McGrath-Hill and Vicas, 1997). In addition, consumption by livestock of the mature plant with seeds has been reported to be fatal.

Nuts from *Aesculus hippocastanum* (horse chestnut; Fig. 26-5) and *Aesculus glabra* (Ohio buckeye) contain a white crystalline coumarin glucoside called esculin. Ingestion by humans causes gastroenteritis, which increases in severity with the number of nuts consumed. Fortunately, esculin is poorly absorbed by the gastrointestinal tract of humans and its systemic effects are usually limited. However, in cattle, esculin may be hydrolyzed in the rumen, resulting in the release of aglycone to cause systemic effects. This can lead to nervous system stimulation—marked by a stiff-legged gait and, in severe poisoning, tonic seizures with opisthotonus (Casteel et al., 1992). The triterpene saponin β-aescin in horse chestnut seed extract may have value in the treatment of venous insufficiency in humans (Siebert et al., 2002).

Antimitotic Effects Podophyllotoxin is found in *Podophyllum peltatum* (May apple, Berberidaceae) especially in its foliage and roots. In low doses, mild purgation occurs; however, overdose results in nausea and severe paroxysmal vomiting (Frasca et al., 1997). By binding microtubules, podophyllotoxin blocks mitosis from proceeding. This has made podophyllotoxin of interest for the treatment of cancer (Schacter, 1996).

Found in the bulbs of *Colchicum autumnale* (autumn crocus, Liliaceae), colchicine blocks the formation of microtubules, ultimately preventing successful mitosis. Ingestion of these bulbs causes severe gastroenteritis (nausea, vomiting, diarrhea, and dehydration). Severe poisoning can result in confusion, hematuria, neuropathy, renal failure, and cardiotoxicity (Mendis, 1989).

Table 26-5

Selective Plants Causing Gastrointestinal Irritation

COMMON NAME	SCIENTIFIC NAME	TOXIC PART	TOXIN
Amaryllis	*Hippeastrum equestre*	Bulb	Lycorine
Barberry	*Berberis vulgaris*	Root	Protoberberine and other isoquinoline alkaloids
Boxwood	*Buxus* sp.	Leaves, stems	Steroidal alkaloids
Buttercup	*Ranunculus* sp.	All parts	Ranunculin, protoanemonin
Crown of thorns	*Euphorbia milii*	All parts	Resiniferatoxin
Daffodil	*Narcissus* sp.	All, especially bulb	Lycorine, narcissin, phenanthridine alkaloids
English Ivy	*Hedera helix*	All parts	Hederin from hederagenin
Euonymus	*Euonymus* sp.	All parts	Alkaloids
Hyacinth	*Hyacinthus orientalis*	Bulb	Calcium oxalate, lycorine
Iris	*Iris*	Bulb	Irritant resin
Mayapple	*Podophyllum peltatum*	Green fruit, roots	Podophyllotoxin
Mistletoe	*Phoradendron flavescens*	Berries, other parts	Phoratoxin
Pokeweed	*Phytolacca americana*	All parts	Phytolaccatoxin, related triterpines
Purging nut	*Jatropha curcas*	Seeds	Jatrophin (curcin) (toxalbumin)
Tung nut	*Aleurites fordii*	Nut	Derivative of phorbol, saponins, toxalbumins
Wiseria	*Wisteria sinensis*	Pods	Wistarine (glycoside)

Figure 26-5. *Aesculus hippocastanum.*

Figure 26-6. *Ricinus communis (castor bean plant).*

Protein Synthesis Inhibition There are many plants that produce ribosomal inhibiting proteins (Bolognesi et al., 2016; Polito et al., 2016). These ribosome-inhibiting proteins are broadly distributed among different plant genera; various tissues express different isoforms and most are single-chain proteins (Schrot et al., 2016). The family Euphorbiaceae contains several genera that are known to be very toxic. The castor bean (*Ricinus communis*; Fig. 26-6) is an ornamental plant that produces seeds that, if eaten by children or adults, causes no symptoms of poisoning for several days after ingestion. Gradually, gastroenteritis develops, resulting in some loss of appetite, with nausea, vomiting, and diarrhea. If a fatal dose is ingested, the gastroenteritis becomes extremely severe and is marked by persistent vomiting, bloody diarrhea, and icterus followed by death within 6 to 8 days. A fatal dose for a child can be as few as 5 seeds and may be as low as 20 seeds for an adult. However, fatality occurs in less than 10% of ingestions when a "fatal" dose is consumed, owing to the fact that the toxic protein is largely destroyed during digestion. There are two lectins found in the beans: ricin I and ricin II of which ricin II is more toxic. Ricin II is made up of an A-chain and a B-chain. The B-chain, composed of

Figure 26-7. *Phytolacca americana (pokeweed).*

262 amino acids, binds terminal galactose residues on cell surfaces allowing the A-chain to be endocytosed (Wu et al., 2006). Once inside, the 267 amino acid A-chain inactivates the 60S ribosomal subunit of cells by catalytic depurination of an adenosine residue within the 28S rRNA, thereby blocking protein synthesis (Bantel et al., 1999; Spooner and Lord, 2015).

The seeds of *Abrus precatorius* (jequirity bean, Leguminosae) contain lectins known as abrins. Abrin-a, one of four isoabrins produced by the plant, has the highest inhibitory effect on protein synthesis and consists of an A-chain and a B-chain (Tahirov et al., 1994). Similar to ricin, the A-chain directly inhibits protein synthesis while the B-chain is responsible for getting the A-chain inside the cell (Ohba et al., 2004). The LD_{50} of abrin when injected in mice is less than 0.1 μg/kg, making abrin one of the most toxic substances known.

Plants that produce only A-chains are not nearly as toxic as those that pair them with a B-chain. Young shoots of pokeweed (*Phytolacca americana*, Phytolaccaceae; Fig. 26-7) can be ingested without toxicity; however, consumption of mature leaves and berries may cause nausea and diarrhea. The plant produces three isozymes of single-chain lectins that are capable of inhibiting protein synthesis in cells and have antiviral properties (Di and Tumer, 2015; Polito et al., 2016). However, these do not readily pass through a cell's membrane but are capable of doing so with the help of a virus (Monzingo et al., 1993).

Wisteria floribunda (Leguminosae) is a common ornamental climbing vine that develops seeds in the fall. Ingestion of these seeds can cause severe gastroenteritis. Just a few seeds can produce

headache, nausea, and diarrhea within hours, followed by dizziness, confusion, and hematemesis (Rondeau, 1993). The toxic lectin binds *N*-acetylglucosamine on mammalian neurons.

Sambucus ebulus (dwarf elder) has medicinal and food properties that are limited by inherent toxicity (Jimenez et al., 2015). Medicinal applications include antioxidant action owing to polyphenols, and inhibition of tumor cell growth by anthocyanidins including cyanidin-3-O-glucoside. Lectins with and without antiribosomal activity have been isolated. Single-chain ribosome-inhibiting proteins have *N*-glycosidase activity on the 28S rRNA subunit, thereby inhibiting polypeptide chain elongation. Ebulin and nigrin have been tested in targeted therapy (Ferreras et al., 2011).

Cardiovascular System

Cardioactive Glycosides The best known cardioactive glycoside is *Digitalis purpurea* (foxglove, Scrophulariaceae; Fig. 26-8). However, squill (*Scilla maritima*), which contains scillaren, and lily of the valley (*Convallaria majalis*), which contains convallatoxin in the bulbs, have actions similar to digitalis. Also, milkweeds (*Asclepias* spp., Asclepiadaceae) contain glycosides (Roy et al., 2005). Other cardiotoxic plants can be found in Table 26-6. The cardiac glycoside desglucouzarin in *Asclepias asperula*, like digitalis, inhibits Na^+,K^+-ATPase (Abbott et al., 1998). Two plants in the Apocynaceae (oleander family) also contain cardioactive glycosides. *Thevetia peruviana* (yellow oleander) is a common ornamental plant in the United States whose seeds contain the highest concentration of cardiac glycosides. The fatal dose to an adult is 8 to 10 seeds (Prabhasankar et al., 1993). Clinical aspects of oleander toxicosis have been described in sheep (Aslani et al., 2004) and humans (Pietsch et al., 2005).

Table 26-6

Selective Plants Causing Cardiotoxicity

COMMON NAME	SCIENTIFIC NAME	TOXIC PART	TOXIN
Azalea	*Rhodendron* sp.	All	Grayanotoxins
Death camus	*Zigadenus* sp.	All	Zygadenine, veratrine
Foxglove	*Digitalis* sp.	Leaves, seeds	Digitalis glycosides
Larkspur	*Delphenium ambiguum*	All	Delphinine
Lily of the valley	*Convallaria majalis*	All	Convallarin, convallamarin
Milkweed	*Asclepias* sp.		(Hydroxycinnamoyl) desglucouzarin
Monkshood	*Aconitum* sp.	Leaves, roots, seeds	Aconitine, aconine
Oleander	*Nerium oleander*	All	Oleandrin, oleandrosine

Figure 26-8. *Digitalis purpurea (common foxglove).*

Figure 26-9. *Veratrum viride (American hellebore).*

Actions on Cardiac Nerves Toxic alkaloids found in *Veratrum viride* (American hellebore, Liliaceae; Fig. 26-9), *Veratrum album* (European hellebore), and *Veratrum californicum* cause nausea, emesis, hypotension, and bradycardia on ingestion. *Veratrum album* has been used for centuries to "slow and soften the pulse." The mixture of alkaloids includes protoveratrine, veratramine, and jervine that affects the heart by causing a repetitive response to a single stimulus resulting from prolongation of the sodium current (Jaffe et al., 1990). The bulbs of the wild camas (*Zigadenus paniculatus*

Figure 26-10. *Rhododendron ponticum (rhododendron).*

and other species of *Zigadenus*, Liliaceae) contain veratrum-like alkaloids (Peterson and Rasmussen, 2003).

Aconitum species, which have been used in western and eastern medicine for centuries, produce the toxic alkaloids aconitine, mesaconitine, and hypoaconitine. Poisoning may occur on ingestion but severity varies with the concentration of the alkaloids, which depends on species, place of origin, time of harvest, and processing procedures (Chan et al., 1994). Along with cardiac arrhythmias and hypotension, ingestion causes gastrointestinal upset and neurological symptoms. The alkaloids work by causing a prolonged sodium current with slowed repolarization in cardiac muscle (Peper and Trautwein, 1967) and in nerve fibers (Murai et al., 1990).

Grayanotoxins are produced exclusively by several genera of Ericaceae (heath family) and in particular they are found in *Rhododendron ponticum* (Onat et al., 1991; Fig. 26-10), *R. macrophyllum* (Casteel and Wagstaff, 1989), and *Kalmia angustifolia* (Burke and Doskotch, 1990). Ingestion of honey contaminated with grayanotoxins, brought by bees, can produce a severe reaction called "mad honey poisoning." The poisoning resembles aconitine poisoning, in that there is bradycardia, hypotension, oral parasthesia, and gastrointestinal upset. Severe poisoning can result in respiratory depression and eventually loss of consciousness. Grayanotoxins bind to sodium channels in cardiac and muscle cells resulting in increased sodium conductance (Maejima et al., 2002).

Vasoactive Chemicals American mistletoe (*Phoradendron flavescens*) and European mistletoe (*Viscum album*, Loranthaceae) are members of the same family and both produce a toxin that is marked for its effect on the cardiovascular system. Both phoratoxin (produced by American mistletoe) and viscotoxin (produced by European mistletoe) cause hypotension, vasoconstriction of the vessels in skin and skeletal muscle, and bradycardia resulting from negative inotropic actions on heart muscle. Phoratoxin is only one-fifth as active as the viscotoxins (Rosell and Samuelsson, 1988). Although serious poisoning from the plants is rare, it is possible to induce anaphylaxis with repeated injections of a mistletoe extract (Bauer et al., 2005).

Ingestion of the fungus *Claviceps purpurea* (ergot), which grows on grains that are used for food, causes vasoconstriction. The "ergot gene cluster" is required for the production of ergot alkaloids (Coyle and Panaccione, 2005; Haarmann et al., 2005). Ergot poisoning was called "St. Anthony's fire" due to the blackened appearance of the limbs of some victims. In extreme cases, the vasoconstriction was severe enough that gangrene would develop in the extremities. Abortion in pregnant women is also common after ingestion of ergot-contaminated grains. *Acremonium coenophialum*, a fungus which grows on the grass tall fescue (*Festuca arundinacea*), produces some ergot alkaloids. Grazing cattle that ingest the contaminated grass develop "fescue toxicosis" (Hill et al., 1994; Blodgett, 2001). This condition results in decreased weight gain, decreased reproductive performance, and increased peripheral vasoconstriction. Pulmonary infection from *Acremonium strictum* has been noted in a horse (Pusterla et al., 2005).

Liver

Hepatocyte Damage Pyrrolizidine alkaloids can be found in *Senecio* (groundsel, Asteraceae) and within four genera of Boraginaceae: *Echium* (bugloss), *Cynoglossum* (hound's tongue), *Heliotropium* (heliotrope), and *Symphytum* (comfrey) (Altamirano et al., 2005; Mei et al., 2005). Ingestion of significant concentrations of these alkaloids causes liver damage in the form of hepatic veno-occlusive disease associated with lipid peroxidation (Bondan et al., 2005). Cattle that graze on grass contaminated with *Senecio* have been found to develop hepatitis that can progress to death if allowed to continue grazing. Human deaths have also been reported in several countries, and in Afghanistan, an epidemic of hepatic veno-occlusive disease arose from consumption of a wheat crop contaminated by *Heliotropium* (Tandon et al., 1978). The liver damage caused by ingestion clinically appears to be similar to cirrhosis and some hepatic tumors that can easily be mistaken to be the source of the disease (McDermott and Ridker, 1990). Consumption of these plants leads to a form of the Budd–Chiari syndrome, which is hallmarked by portal hypertension and obliteration of the small hepatic veins. Human consumption can occur from drinking "comfrey tea" that contains *Symphytum* (Rode, 2002). There are species differences in metabolism of the pyrrolizidine alkaloids (Huan et al., 1998).

Lantana camara (Verbenaceae), a shrub native to Jamaica, has been shown to poison livestock, particularly in India. Cattle grazing on the plant develop bile-related disorders including cholestasis and hyperbilirubinemia. Several triterpenoids have been isolated from the plant and, in particular, lantadene A (22-β-angeloyloxy-3-oxo-olean-12-en-28-oic acid) has been shown to be hepatotoxic (Sharma et al., 1991).

Mushroom Toxins Most nonedible mushrooms may cause mild discomfort and are not life threatening; however, repeated ingestion of the false morel, *Gyromitra esculenta*, has been found to cause hepatitis (Michelot and Toth, 1991). The toxin gyromitrin is inactivated generally by boiling. Most fatal poisonings related to wild mushrooms are from ingestion of different species within *Amanita*, *Galerina*, and *Lepiota* (Karlson-Stiber and Persson, 2003). The dangerousness of *Amanita phalloides* (Fig. 26-11) and *Amanita ocreata* is why they are named "death cap" and "death angel," respectively. Two types of toxins, phalloidin and amatoxins, can be found within *A. phalloides*. Phalloidin is capable of binding actin in muscle cells; however, it is not readily absorbed during digestion, which limits its harmful effects (Cappell and Hassan, 1992). Parenterally administered phalloidin produces toxicity in wild-type mice but not in Oatp1b2-null mice, which is consistent with phalloidin being a substrate for uptake into hepatocytes by the Oatp1b2 carrier (Lu et al., 2008). Unfortunately, α-, β-, and γ-amanitins are readily absorbed due to being molecularly much

Figure 26-11. *Amanita phalloides (death cap).*

smaller than phalloidin. Of the amatoxins, α-amanitin is the most toxic as it inhibits protein synthesis in hepatocytes by binding to RNA polymerase II (Jaeger et al., 1993). In addition to the liver, the intestinal mucosa and kidneys are also affected and serious clinical signs develop about 3 days after ingestion. In cases of severe poisoning, a liver transplant may be required. Amatoxin-α irreversibly inhibits acetylcholinesterase (Hyde and Carmichael, 1991).

Mycotoxins Fumonisin toxins are produced by the fungus *Fusarium* that is known to grow on corn. Consumption of contaminated corn by horses leads to equine leukoencephalomalacia that is marked by lethargy, ataxia, convulsions, and ultimately death (Norred, 1993). The liver is the most affected organ in many species including horses, pigs, chickens, and rats (Riley et al., 1994). Ingestion in humans has been suggested to be associated with esophageal cancer (Yoshizawa et al., 1994). Fumonisins are diesters of propane-1,2,3-tricarboxylic acid and a pentahydroxyicosane containing a primary amino acid (Gurung et al., 1999) that is similar to sphingosine. This similarity is responsible for their toxicity as they block the enzymes involved in sphingolipid biosynthesis (Norred, 1993). In contrast, mycoestrogenic zearalenone induces CYP3A enzymes (Ding et al., 2006). Aflatoxin B1 has been shown to form guanine adducts and induce apoptosis in human hepatocytes (Reddy et al., 2006).

Kidney and Bladder

Carcinogens The bracken fern (*Pteridium aquilinum*), which is extremely common worldwide, is the only higher plant known to be carcinogenic in animals under natural feeding conditions. The commonest bladder tumors in cattle are epithelial and mesenchymal neoplasms (Kim and Lee, 1998). Ptaquiloside, a norsesquiterpene glucoside, is the known carcinogen present in the fern and it has been found to alkylate adenines and guanines of DNA (Shahin et al., 1999; Rasmussen et al., 2003). Bovine consumption of bracken fern has been shown to significantly increase chromosomal aberrations (Lioi et al., 2004). In addition, evidence has been found that consumption of young bracken fern shoots by humans is associated with cancers of the mouth and throat (Alonso-Amelot and Avendano, 2002).

Kidney Tubular Degeneration Species of *Xanthium* (cocklebur, Asteraceae) have been found to contain the toxin carboxyatractyloside, which causes microvascular hemorrhages in multiple organs (Turgut et al., 2005). Livestock poisoning has been noted to cause the outward signs of depression and dyspnea; however, internally the toxin causes tubular degeneration and necrosis in the kidney and centrilobular necrosis in the liver (del Carmen Mendez et al., 1998).

Consumption of the mushroom species *Cortinarius* has been found to cause acute renal failure but different species vary widely in toxicity and, therefore, edibility. In an investigation of a series of 135 poisonings related to *Cortinarius* ingestion, where death occurred in almost 15% of the cases, renal biopsy showed acute degenerative tubular lesions with inflammatory interstitial fibrosis (Bouget et al., 1990). *Cortinarius orellanus* and *C. rubellus* (Fig. 26-12) contain the deadly toxin orellanin, which triggers renal failure. Table 26-7 lists the common and scientific names and toxins for selective plants that are capable of inducing nephrotoxicity.

Figure 26-12. *Cortinarius rubellus (deadly webcap).*

Table 26-7
Selective Plants Producing Nephrotoxicity

COMMON NAME	SCIENTIFIC NAME	PART	TOXIN
Autumn crocus	*Colchicum autumnale*	Bulb	Colchicine
Castor bean	*Ricinus communis*	All	Ricin, recinine
Daphne	*Daphne mezereum*	Leaves, fruits	Daphnin, mezerein (diterpenoid)
Impila	*Callilepis laureola*	Tubers	Atractyloside
Mushrooms	*Amanita phalloides*	All	Amatoxin
	Cortinarius sp.	All	Orellanine
Water hemlock	*Cicuta maculata*	Roots	Cicutoxin

Blood and Bone Marrow

Anticoagulants Fungal infections in sweet clover (*Melilotus alba*) have been found to produce dicumarol, a coumarin derivative that is a potent anticoagulant. Deaths in cattle have been reported and are caused by hemorrhages (Puschner et al., 1998). The dicumarol derivative warfarin is a widely used rodenticide and as an anticoagulant drug.

Bone Marrow Genotoxicity *Argemone* (Papaveraceae), a species of poppy, produces sanguinarine, a benzophenanthridine alkaloid that is known to intercalate DNA and have carcinogenic potential (Das et al., 2005). Studies in mice have shown that a single low dose of argemone oil increases chromosomal aberrations in bone marrow cells (Ansari et al., 2004).

Cyanogens Cyanogens are found in a wide variety of plants including the kernels of apples, cherries, and peaches. The highest concentrations are found in the seeds of the bitter almond, *Prunus amygdalus* var *amara*. However, small children are susceptible to amygdalin poisoning if they consume sufficient peach (*Prunus persica*) kernels. Fortunately, the concentration present in the seeds of apples is low enough that they are unlikely to cause a problem. Metabolism of amygdalin releases hydrocyanic acid that binds to the ferric ion in methemoglobin and the cytochrome oxidases, which, if severe enough, results in cyanide poisoning with death from asphyxiation (Bromley et al., 2005; Jorgensen et al., 2005). Severe cyanide poisoning can occur with cyanogen-containing vitamin supplements (O'Brien et al., 2005).

Cassava produced from *Manihot esculenta* (Euphorbiaceae) is a major food source for some regions of Africa. The raw root contains a cyanogenic glucoside linamarin that degrades during processing of the root for human consumption. Unfortunately, local processing may be inadequate and that can lead to ingestion of linamarin. Chronic ingestion has been suggested to be the cause of epidemics of konzo, a form of tropical myelopathy with sudden onset of spastic paralysis (Tylleskar et al., 1992).

Nervous System

Epileptiform Seizures The common and scientific names for selective plants that produce neurotoxins can be found in Table 26-8. Within the family Apiaceae, which contains carrots, the fleshy tubers of *Cicuta maculata* (water hemlock; Fig. 26-13) produce neurotoxic cicutoxin (a C17-polyacetylene). Consumption of a single tuber can result in fatal poisoning, characterized by tonic–clonic convulsions, owing to the cicutoxin binding to GABA-gated chloride channels (Uwai et al., 2000).

Members of the mint family (Labiatae) such as pennyroyal (*Hedeoma*), sage (*Salvia*), and hyssop (*Hyssopus*) are well known for their essential oils containing monoterpenes. Ingestion of these monoterpenes in concentrations much higher than those used for flavoring can cause tonic–clonic convulsions. In particular, menthol is a selective modulator of inhibitory ligand-gated channels (Hall et al., 2004).

Certain species within *Strychnos* (Loganiaceae) produce strychnine and brucine, which are known to cause increased central nervous system (CNS) stimulation by blocking glycine-gated chloride channels. *Strychnos nux vomica*, a small tree native to India, produces seeds that have been implicated in cases of unintentional poisoning (Wang et al., 2004).

Excitatory Amino Acids Red algae (*Digenia simplex*) under certain conditions can proliferate rapidly leading to the notorious beach vacating "red tide" and producing kainic acid. Kainic acid

Table 26-8

Selective Plants Producing Neurotoxicity

COMMON NAME	SCIENTIFIC NAME	PART	TOXIN	MECHANISM
Acacia tree	*Acacia willardiana*	Seeds	Willardiine	Glutamate receptor agonist
Alga	*Digenea simplex* *Chondria armata*	All	Kainic acid Domoic acid	Depolarization of glutamate-gated channels
Betel nut	*Areca catechu*	Nut	Guvacine Arecoline	GABA uptake inhibitor, anticonvulsant Stimulates muscarinic cholinoceptors; CNS stimulation
Buckthorn; Coyotillo	*Karwinskia humboldtiana*	Seeds, leaves	Tullidinol	Demyelination of motor neurons leading to paralysis
Chrysanthemum	*Chrysanthemum cinerarifolium*	Seeds	Pyrethrins	Stimulate sodium efflux from neurons in insects
Deadly nightshade	*Atropa belladonna*	Berries	Tropine alkaloid	Blockade of muscarinic cholinoceptors
Fly agaric mushroom	*Amanita muscaria*	All	Muscarine Muscimol	Stimulates muscarinic cholinoceptors; CNS stimulation GABA receptor agonist
Rhododendron	*Rhododendron* sp.	Leaves	Grayanotoxins	Stimulate sodium channel and membrane depolarization
Ryania	*Ryania speciosa*	Stems	Ryanodine	Stimulates calcium channels and muscle contraction
Poison nut tree	*Strychnos nux vomica*	All, especially seeds	Strychnine	Glycine receptor antagonist that produces convulsions
Tobacco	*Nicotiana tabacum*	Leaves	Nicotine	Nicotinic cholinoceptor agonist (low doses) or antagonist (high doses); CNS stimulation

Figure 26-13. *Cicuta maculata (water hemlock).*

Figure 26-14. *Amanita muscaria (fly agaric).*

may be ingested by humans who eat filter-feeding mussels that have eaten red algae. Acute symptoms are most notably gastrointestinal distress, headache, hemiparesis, confusion, and seizures. Severe exposure can result in severe memory deficits and sensorimotor neuropathy (Teitelbaum et al., 1990). Isodomoic acid from *Nitzschia* sp. has seizure-inducing properties (Kotaki et al., 2005).

The fungi *Amanita muscaria* (fly agaric; Fig. 26-14) and *Amanita pantherian* (panther agaric) produce the excitatory amino acid ibotenic acid (isoxazole amino acid) and its derivative muscimol that is neurotoxic (Li and Oberlies, 2005). Poisoning produces CNS depression, ataxia, hysteria, and hallucinations. Myoclonic twitching and seizures sometimes develop (Benjamin, 1992). Other genera of fungi have been marked for their hallucinogenic actions, notably *Psilocybe*, which contains psilocin and psilocybin (Tsujikawa et al., 2003).

Willardiine, an agonist on glutamate receptors, has been isolated from *Acacia willardiana*, *Acacia lemmoni*, *Acacia millefolia*, and *Mimosa asperata* (Gmelin, 1961) and causes excitation of the nervous system. Seeds from the legume *Lathyrus sativus* (grass pea) also contain an excitatory amino acid known as β-*N*-oxalyl-L-α,β-diaminopropionic acid (Warren et al., 2004). Consumption of seeds over long periods can cause lathyrism with severe spastic muscle weakness and atrophy but little sensory involvement. Thiocyanate from linamarin can stimulate neuronal glutamate receptors, leading to degeneration of corticospinal motor pathways (Spencer, 1999).

Motor Neuron Demyelination *Karwinskia humboldtiana* is a shrub found in the southwestern United States, Mexico, and Central America that produces anthracenones in its seeds. Both human and livestock poisonings have been known to occur. Several days following ingestion, ascending flaccid paralysis develops with demyelination of large motor neurons in the legs and eventually leads to bulbar paralysis in fatal cases (Martinez et al., 1998). In addition to neurotoxicity, the anthracenones in *Karwinskia*, especially peroxisomicine A_2, cause lung atelectasis, emphysema, and massive liver necrosis. Inhibition of catalase in peroxisomes has been proposed as the mechanism of cell toxicity (Martinez et al., 1997).

Cerebellar Neurons The legumes *Swainsonia cansescens*, *Astragalus lentiginosus* (spotted locoweed), and *Oxytropis sericea* (locoweed) produce a toxic indolizidine alkaloid called swainsonine. These weeds can be accidentally consumed by grazing cattle, causing aberrant behavior with hyperexcitability and locomotor difficulty (James et al., 1991). In fatal cases, there is cytoplasmic foamy vacuolation of cerebellar neurons. Swainsonine causes marked inhibition of liver lysosomal and cytosomal α-mannosidase and Golgi mannosidase II resulting in abnormal accumulation of brain glycoproteins and mannose-rich oligosaccharides that ultimately causes cell death (Tulsiani et al., 1988). *Embellisia* fungi from locoweed produce a locoweed-like toxicosis (McLain-Romero et al., 2004).

Parasympathetic Stimulation Certain mushrooms of the genera *Inocybe*, *Clitocybe*, and *Omphalatus* contain significant amounts of muscarine, which mimics the action of acetylcholine, the principal neurotransmitter in the parasympathetic nervous system. Consumption of any of these species results in extreme parasympathetic activation resulting in miosis, diarrhea, sweating, salivation, lacrimation, urination, bradycardia, and bronchoconstriction (de Haro et al., 1999).

Parasympathetic Block Atropine, L-hyoscyamine, and scopolamine are belladonna alkaloids that can be found in varying concentrations in several genera of Solanaceae such as *Datura stramonium* (jimson weed; Fig. 26-15), *Hyoscyamus niger* (henbane), *Atropa belladonna* (deadly nightshade; Fig. 26-16), and *Duboisia myoporoides* (pituri). These alkaloids all effectively block the muscarinic receptor, essentially turning off the parasympathetic drive at

Figure 26-15. *Datura stramonium (jimson weed).*

Figure 26-16. *Atropa belladonna (deadly nightshade).*

the target organ. This explains why tachycardia, dry mouth, dilated pupils, and decreased gastrointestinal motility all occur on ingestion of these toxins. Of the three alkaloids, scopolamine is the most potent; however, sizable doses of L-hyoscyamine or atropine can produce similar effects. Large doses can cause confusion, bizarre behavior, hallucinations, and subsequent amnesia, and in severe intoxication, tachycardia may be completely absent (Caksen et al., 2003).

The seeds of *Solanum dulcamara* (bittersweet, which is often used in flower arrangements) contain the glycoalkaloid solanine that on ingestion causes tachycardia, dilated pupils, and hot and dry skin—symptoms similar to atropine poisoning (Ceha et al., 1997).

Sensory Neuron Block Capsaicin found in *C. annuum* (sweet pepper) and *C. frutescens* (red pepper) causes a burning sensation on vanilloid-type (VR1) sensory receptors. It also desensitizes the transient receptor potential vanilloid 1 (TRPV1) receptor of sensory endings of C-fiber nociceptors to stimuli, a property that has therapeutic use in treating chronic pain (Szalcsany, 2002). Capsaicin also can relax ileal smooth muscle (Fujimoto et al., 2006). Fortunately, desensitization produced by capsaicin is not due to cell death (Dedov et al., 2001). Polygodial, a sesquiterpene found in *Polygonum hydropiper*, also desensitizes the TRPV1 (Andre et al., 2006), whereas resiniferatoxin activates TRVP1 (Raisinghani et al., 2005). Pyrethum from chrysanthemum flowers blocks sodium channels in the insect nervous system (McGovern and Barkley, 1999).

Skeletal Muscle and Neuromuscular Junction

Neuromuscular Junction Anabasine, an isomer of nicotine, is present in *Nicotiana glauca* (tree tobacco, Solanaceae) and produces prolonged depolarization of the junction after a period of excessive stimulation. Consumption of *N. glauca* leaves can result in flexor muscle spasm and gastrointestinal irritation, followed by severe, generalized weakness, and respiratory compromise (Mellick et al., 1999). Curare, which is used as a poison placed on the tips of arrows, is also a potent neuromuscular blocking agent and is obtained from tropical species of *Strychnos toxifera* and *Chondrodendron tomentosum*. *Anabaena flosaquae*, a species of alga, can produce under the right conditions a neurotoxin anatoxin A that is known to be fatal. Anatoxin A, ingested by animals that drink pond water with the alga present, depolarizes and blocks the animal's nicotinic and muscarinic acetylcholine receptors, which can cause death from respiratory arrest within minutes to hours (Short and Edwards, 1990).

Delphinium barbeyi (tall larkspur, Ranunculaceae), which grows naturally in the western United States, contains methyllycaconitine. Ingestion of the toxin by cattle results in muscle tremors and ataxia followed by prostration and can ultimately lead to respiratory arrest in fatal cases. Methyllycaconitine is similar to curare, in that it has a high affinity for the acetylcholine receptor at the neuromuscular junction. Physostigmine, an inhibitor of acetylcholinesterase that increases acetylcholine at the neuromuscular nicotinic receptor, has been used successfully as an antagonist to treat some cases of methyllycaconitine poisoning (Pfister et al., 1994).

Skeletal Muscle Damage Certain species of *Thermopsis* produce seeds that contain quinolizidine alkaloids. Human poisoning from eating the seeds is rare, but cases have been reported in young children who experienced abdominal cramps, nausea, vomiting, and headache lasting up to 24 hours (Spoerke et al., 1988). Livestock grazing on *Thermopsis montana* (false lupine, mountain goldenbanner; Fig. 26-17) develop locomotor depression and recumbency due to areas of necrosis in skeletal muscle that have been found on autopsy (Keeler and Baker, 1990).

Consumption of *Cassia obtusifolia* (sicklepod, Leguminosae) seeds by livestock causes a degenerative myopathy in cardiac and skeletal muscle. Extracts of *C. obtusifolia* have been found to inhibit NADH-oxidoreductase in bovine and swine mitochondria in vitro (Lewis and Shibamoto, 1989).

White snakeroot (*Ageratina altissima*, Asteraceae; Fig. 26-18), a common plant in the central and western United States, can be accidentally eaten by grazing cattle. On ingestion, the cattle exhibits tremors and humans who drink the milk of an affected cow can get "milk sickness" (Beier et al., 1993). The toxic effects are attributed to tremetone, a benzofuran, which blocks gluconeogenesis from lactate, resulting in acidosis, tremor, and ultimately death (Polya, 2003).

Bone and Tissue Calcification

Bone and Soft Tissue Consumption of *Solanum malacoxylon* (Solanaceae) by sheep and cows can cause a marked decrease in bone calcium and calcification of the entire vascular system due to the presence of a water-soluble vitamin D–like substance. In severe

Figure 26-17. *Thermopsis montana (mountain goldenbanner).*

Figure 26-18. *Ageratina altissima (white snakeroot).*

cases other organs can also be affected such as the lungs, joint cartilage, and kidney.

Consumption of *Cestrum diurnum* (day-blooming jasmine, Solanaceae) and *Cestrum laevigatum* has been found to cause hypercalcemia and soft tissue calcification in grazing cattle (Durand et al., 1999) and chickens (Mello and Habermehl, 1992), which is due to the presence of a dihydroxyvitamin D_3 glycoside in the leaves (Durand et al., 1999). Hay that had been contaminated with *C. laevigatum* caused a marked centrilobular and midzonal hepatic necrosis in goats (Peixato et al., 2000).

Reproduction and Teratogenesis

Abortifacients Besides its actions on the nervous system, swainsonine, the active alkaloid in the legumes *Astragalus* and *Oxytropus*, also causes abortions in pregnant livestock that accidentally ingest locoweeds (Bunch et al., 1992).

Foliage and seeds of *Leucaena leucocephala*, *Leucaena glauca*, and *Mimosa pudica* contain a toxic amino acid, mimosine, which on ingestion by cattle leads to uncoordinated gait, goiter, and reproductive disturbances including infertility and fetal death (Kulp et al., 1996). Mimosine has been found to arrest the cell cycle in late G1 phase that helps explain its toxic effects (Perry et al., 2005).

Lectins present in bitter melon seeds (*Momordica charantia*, Cucurbitaceae) have antifertility, abortifacient, and embryotoxic actions on ingestion. Components of the lectins known as momorcharins are known to induce midterm abortion in humans (Wang and Ng, 1998).

Caulophyllum thalictroides (blue cohosh, Berberidaceae) contains a toxin known as caulophylline that is teratogenic in rats (Kennelly et al., 1999) and herbal preparations of blue cohosh have been used to terminate pregnancy (Jones and Lawson, 1998). In fact, nicotine toxicity may result from blue cohosh use as an abortifacient (Rao and Hoffman, 2002).

Teratogens Ingestion of *V. californicum* (California false hellebore, Liliaceae; Fig. 26-19) by pregnant sheep is known to cause malformations in its offspring that can include cyclopia, exencephaly, and microphthalmia. As with most teratogens, the severity of malformations depends on what developmental stage the fetus is in at the time of exposure. Limb defects are common with exposure during the fourth to fifth weeks of gestation; fetal stenosis of the trachea will occur with ingestion on days 31 to 33 (Omnell et al., 1990). Many other species of animals are susceptible to *V. californicum* poisoning, including cows, goats, chickens, rabbits, rats, and mice (Omnell et al., 1990), hamsters (Gaffield and Keeler, 1993), lambs (Keeler, 1990), and rainbow trout embryos (Crawford and Kocan, 1993). The toxic alkaloid called jervine causes teratogenesis by blocking cholesterol synthesis that, among other things, prevents a proper response of fetal target tissue to the sonic hedgehog gene (Shh). Shh has an important role in proper developmental

Figure 26-19. *Veratrum californicum (California false hellebore).*

patterning of head and brain, and blocking cholesterol synthesis has been shown experimentally to cause a loss of midline facial structures (Cooper et al., 1998).

Pregnant cattle grazing on *Lupinus caudatus* and *Lupinus formosus* (lupines, Leguminosae), *N. glauca* (tree tobacco, Solanaceae), and *Conium maculatum* (poison hemlock, Solanaceae) have been found to experience a myriad of fetal deformations if ingestion occurs during a sensitive gestational period. The toxic alkaloids in these plants are anagyrine (*L. caudatus*), ammodendrine (*L. formosus*), anabasine (*N. glauca*), and coniine (*C. maculatum*; Forsyth et al., 1996). It is thought that these alkaloids depress fetal movements that can lead to malformations (Lopez et al., 1999).

CLINICAL STUDY OF PLANT POISONS

Recent research concerning the use of plant toxins in a clinical setting has blossomed (Ball and Kowdley, 2005). A number of factors make plant toxins of particular interest, including their diverse effects, availability, and cost. With a growing group of people who wish to return to a more "natural" way of life, a medicine that is derived straight from a plant is much more marketable than one that is completely chemically synthesized. For example, root extract of the African Uzara plant has been used as an antidiarrheal remedy for centuries; however, its mechanism of action was only speculative. Recent research has shown that Uzara root extract reduced chloride secretion by the gut specifically by inhibiting Na^+,K^+-ATPase. This effect was seen even in the presence of cholera toxin that causes potent diarrhea by increasing chloride secretion in the gut (Schulzke et al., 2011). Interestingly, anemonin, which is the active skin irritant produced by species of *Ranunculus* (buttercup), has been found to show potent anti-inflammation effects under certain conditions. The compound was found to reduce nitric oxide production that resulted in a lessened inflammatory response to inflammatory stimuli (Lee et al., 2008). This mechanism could provide a new anti-inflammatory treatment modality and is being tested for possible medical use. Silymarin and usnic acid may have promise as anticancer drugs (Mayer et al., 2005a, 2005b). Finally, native Nigerians use an extract from *M. pruriens* seeds as a pretreatment for snakebites from *Naja sputatrix* (Javan spitting cobra). When tested in rats, the seed extract helped protect against the cardiorespiratory and neuromuscular depressant effects of the snake venom (Fung et al., 2011). A recent review on the ethnopharmacology of aconitine, strychnine, scopolamine, and anisodamine contrasted the medicinal value of these chemicals with their high toxicity (Ma et al., 2015). In addition, tenuifolide B, which is extracted from the stem of the plant Cinnamomum tenuifolium, may selectively reduce cell viability of oral cancer cells (Chen et al., 2016). These toxic plants have great potential for pain reduction and other purposes. Thus, old herbal remedies are a ripe field of study, for many of their effects can be beneficial yet toxic at high enough concentrations. A goal for new research is to elucidate the mechanism of action so that treatments can be tailored to the individual needs and toxic effects can be avoided or interactions with conventional drugs can be minimized (Izzo and Ernst, 2001). As our knowledge of plant toxins and their mechanisms of action expands, the number of new and clinically useful plant remedies and medical products is bound to increase (Polito et al., 2016). Technological advances in chemical purification and identification will permit better toxic characterization as well (Arilla et al., 2006).

Plant engineering with ribosome-inhibiting proteins can increase resistance to pests and microbial pathogens. Moreover, conjugation with carriers such as antibodies and nanoparticles can help direct the active protein to target cells for destruction, such as cancer cells (Gilabert-Oriol et al., 2014; Pizzo and Di Maro, 2016). A challenge to the use of these ribosomal inhibitor-conjugates, or immunotoxins, is that endosomal destruction can occur upon entry into target cells. Considerable effort to produce endosomal escape enhancers has been reviewed (Fuchs et al., 2016). These enhancers may work by increasing cell penetrance, protection of the catalytic domain, conversion to secondary metabolites, and complexing with light-sensitive substances for activation. Of more than 500-targeted toxins from disparate species, very few have been approved for therapeutic application (Fuchs et al., 2016).

SUMMARY OF PLANT TOXICITIES

Toxic chemicals produced by plants can cause something as innocuous as a mild rash on the skin all the way to death by respiratory arrest. It is important to remember that these toxins are primarily defense mechanisms against natural predators. However, we benefit greatly from plants as many have produced potent antibiotics and pharmacologic therapies for myriad diseases that afflict humans.

INTRODUCTION TO ANIMAL VENOMS

The animal kingdom consists of more than 100,000 species spread through major phyla including arthropods, mollusks, and chordates (Mebs, 2002). Venomous animals are capable of producing a poison in a highly developed exocrine gland or group of cells and can deliver their toxin during a biting or stinging act. The venom is the sum of all natural venomous substances produced in the animal (Ménez et al., 2006). Conversely, poisonous animals have no specific mechanism or structure for the delivery of their poisons, and poisoning usually takes place through ingestion. Venomous or poisonous animals are widely distributed throughout the animal kingdom, from the unicellular protistan *Alexandrium* (*Gonyaulax*) to certain mammals, including the platypus and the short-tailed shrew. At least 400 species of snakes are considered dangerous to humans. Myriad venomous and poisonous arthropods exist, and toxic marine animals are found in almost every sea and ocean (Russell and Nagabhushanam, 1996; Mebs, 2002; Mackessy, 2010).

Animal venom may play a role in offense (as in the capture and digestion of food), in the animal's defense (as in protection against predators or aggressors), or in both functions. Venoms used in an offensive posture are generally associated with the oral pole, as in the snakes and spiders, while those used in a defensive function are usually associated with the aboral pole or with spines, as in the stingrays and scorpion fish. In the snake, the venom provides a food-getting mechanism. Its secondary function is its defensive status. In contrast, in venomous spiders, toxin is used to paralyze the prey before the extraction of hemolymph and body fluids. The venom is not primarily designed to kill the prey, but it is only to immobilize the organism for feeding. The same can be said for scorpions, although they do use their venom in defense. In fish, such as the scorpion fish and stone fish, and in elasmobranches, such as the stingray, the venom apparatus is generally used in the animal's defense. In contrast, poisonous animals usually derive their toxins through the food chain. As such, poison is often a metabolite produced by microorganisms, plants, or animals. Poisons are sometimes concentrated as they pass through the food chain from one animal to another. It is also worth noting that animal and plant toxins tend to differ significantly in their chemical complexity, yet both are capable of causing massive harm. Plant toxins tend to be smaller compounds or proteins, and often times a single offending substance can be pinpointed. Conversely, animal toxins must be studied in the context of the entire venom or poison that typically is very complex and contains many individual toxic compounds and very large proteins that essentially work together to cause their effects. Just the same as the preceding section on plant toxins, certain criteria were employed to effectively narrow down the animal toxins discussed. Specifically considered were how often does human exposure occur, how significant is an exposure, and in general how much is known about the animal's toxic properties.

PROPERTIES OF ANIMAL TOXINS

Venoms are very complex, containing polypeptides, high- and low-molecular-weight proteins, amines, lipids, steroids, aminopolysaccharides, quinones, glucosides, and free amino acids, as well as serotonin, histamine, and other substances. Some venoms are known to consist of more than a hundred proteins. The venom is a source of peptides and proteins that act on myriad exogenous targets such as ion channels, receptors, and enzymes within cells and on cell membranes (Ménez et al., 2006). Studying venom is important for several reasons. First, venoms offer valuable insight into the systems they act on such as the cardiovascular system, nervous system, coagulation, and homeostasis. Second, venoms are useful as a source of potential new drugs, with at least five chemicals already on the market and dozens undergoing preclinical or clinical trials. Third, a greater understanding of venoms favors development of improved protection against envenomation (Ménez et al., 2006).

Novel instrument developments have permitted the greater application of mass spectrometry, coupled with various separation technologies, to tease out the complexity of natural venoms, thereby identifying the peptide and protein components of venoms (Escoubas, 2006). The technology allows considerable resolution of extremely small amounts of venom. Fig. 26-20 demonstrates the application of gel filtration and high-pressure liquid chromatography (HPLC), as cone snail venom was fractionated into numerous peptides with varying activities (Olivera et al., 1990). Similar fractionations have been performed on many other types of venom to identify the individual components. Unfortunately, studying the chemistry, pharmacology, and toxicology of venoms requires isolating and dismantling the venoms and losing the synergy among multiple components. Nevertheless, advanced technology will permit peptide sequencing, and the characterization of posttranslational modifications, such as glycosylation, and the discovery of new pharmacophores. Most venoms probably exert their effects on almost every cell and tissue, and their principal pharmacologic properties are usually determined by the amount of a fraction that accumulates at an activity site. Table 26-9 reveals the extremely large range in the LD_{50} of different toxic compounds and venoms injected intravenously into mice.

The bioavailability of a venom is determined by its composition, molecular size, amount or concentration gradient, solubility, degree of ionization, and the rate of blood flow into that tissue, as well as the properties of the engulfing surface itself. The venom can be absorbed by active or passive transport, facilitated diffusion, or pinocytosis, among other physiologic mechanisms. Besides the bloodstream, the lymph circulation not only carries surplus interstitial fluid produced by the venom but also transports larger molecular components and other particulates back to the bloodstream. Thus, the larger toxins of snake venoms, particularly those of Viperidae, probably enter the lymphatic network preferentially and then are transported to the central venous system in the neck (Russell, 2001). Because lymphatic capillaries, unlike blood capillaries, lack a basement membrane and have fibroelastic "anchoring filaments," they can readily adjust their shape and size, facilitating absorption of excess interstitial fluid along with macromolecules contained in a venom.

The site of action and metabolism of venom is dependent on its diffusion and partitioning along the gradient between the plasma and the tissues where the components are deposited. Once the toxin reaches a particular site, its entry to that site is dependent on the rate of blood flow into that tissue, the mass of the structure, and the partition characteristics of the toxin between the blood and the particular tissue. Receptor sites appear to have highly variable degrees of sensitivity. In the case of complex venoms, there may be several, if not many, receptor sites. There is also considerable variability in the sensitivity of those sites for the different components of a venom.

A venom may also be metabolized in several or many different tissues before undergoing excretion. Some venom components are metabolized distant to the receptor site(s) and may never reach the primary receptor in a quantity sufficient to affect that site. The amount of a toxin that tissues can metabolize without endangering the organisms may also vary. Organs or tissues may contain enzymes that catalyze a host of reactions, including deleterious ones. Once a venom component is metabolically altered, the end substance is excreted primarily through the kidneys. The intestines

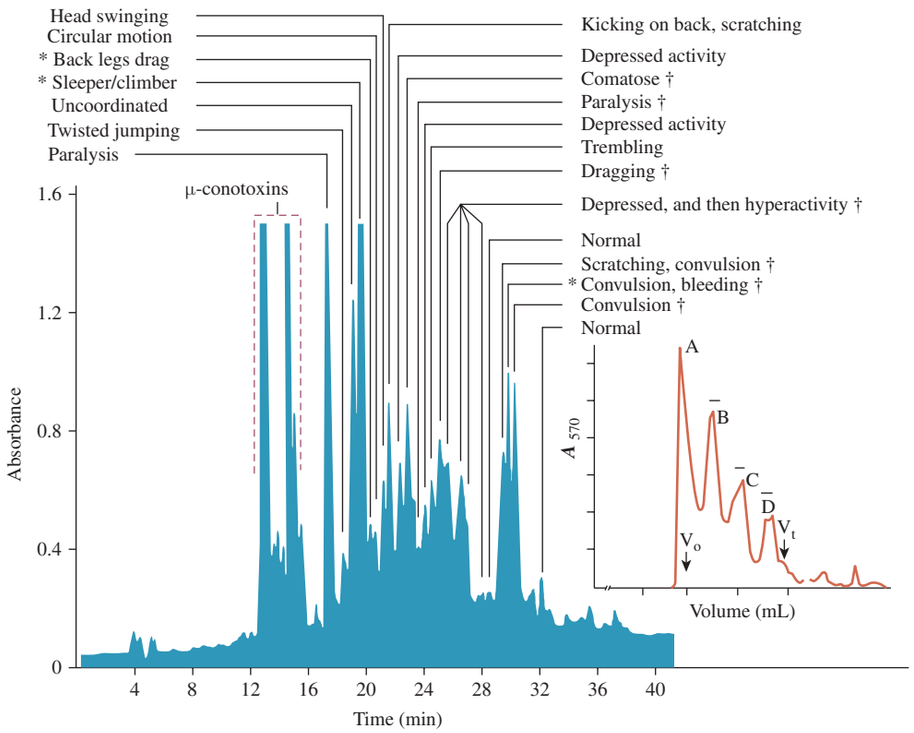

Figure 26-20. *Multiple biologically active components were obtained from Conus geographus venom by first subjecting the venom to gel filtration on Sephadex G-25 into four fractions and then separation of fraction B (which contains the α-conotoxins) by high-pressure liquid chromatography on a VYDAC C18 column using a trifluoroacetic acid–acetonitrile gradient.* Various peak fractions were then injected intracerebrally into mice and different responses were noted. (†) The fraction was lethal in at least one injected animal. (Reprinted with permission from Olivera et al. [1990].)

Table 26-9

Intravenous LD_{50} Values of Selected Toxins Determined in Mice

TOXIN SOURCE	COMMON NAME	LD_{50} (μg/kg)
Clostridium botulinum	Botulinum toxin	0.0003
Crotalus viridis helleri	Southern pacific rattlesnake	1.3
Crotalus adamanteus	Eastern diamondback	1.5
Oxyuranus scutellatus	Australian taipan	2
Crotalus atrox	Western diamondback	2.2
Agkistrodon piscivorus	Eastern cottonmouth	4
Agkistrodon contortrix	Copperhead	11
Androctonus australis	North African scorpion	17
Notechis scutatus	Australian tiger snake	25
Naja siamensis	Indochinese spitting cobra	75

SOURCES: Data from Mebs (2002) and Russell (2001).

play a minor role, and the contributions by the lungs and biliary system have not been determined. Excretion may be complicated by the direct action of the venom on the kidneys themselves.

ARTHROPODS

There are more than 1 million species of arthropods, generally divided into 25 orders, of which only about 10 orders are of significant venomous or poisonous importance. These include the arachnids (scorpions, spiders, whip scorpions, solpugids, mites, and ticks), the myriapods (centipedes and millipedes), the insects (water bugs, assassin bugs, and wheel bugs), beetles (blister beetles), Lepidoptera (butterflies, moths, and caterpillars), and Hymenoptera (ants, bees, and wasps). Several texts and papers that deal with venomous and poisonous arthropods are available (Piek, 1986; Cohen and Quistad, 1998; Russell, 2001; Kuhn-Nentwig, 2003; Isbister et al., 2004; Heinen and Gorini da Veiga, 2011).

The number of deaths from arthropod stings and bites is unknown. In Mexico, parts of Central and South America, North Africa, and India, deaths from scorpion stings, for instance, exceed several thousand a year. Spider bites probably do not account for more than 200 deaths a year worldwide. A common problem faced by physicians in suspected spider bites relates to the differential diagnosis. The arthropods most frequently involved in the misdiagnoses were ticks (including their embedded mouthparts), mites, bedbugs, fleas (infected flea bites), Lepidoptera insects, flies, vesicating beetles, water bugs, and various stinging Hymenoptera. Among the disease states that were confused with spider or arthropod bites or stings were erythema chronicum migrans, erythema

nodosum, periarteritis nodosum, pyroderma gangrenosum, kerion cell-mediated response to a fungus, Stevens–Johnson syndrome, toxic epidermal necrolysis, herpes simplex, and purpura fulminans. Any arthropod may bite or sting and not eject venom. Finally, some arthropod venom poisonings accentuate the symptoms and signs of an existing undiagnosed subclinical disease that further complicates diagnosis.

ARACHNIDA

Scorpions

Of the more than 1000 species of scorpions, the stings of more than 75 can be considered of sufficient importance to warrant medical attention (Keegan, 1980; Polis, 1990; Russell, 2001). Some of the more important scorpions are noted along with their location in Table 26-10. In addition, members of the genera *Pandinus*, *Hadrurus*, *Vejovis*, *Nebo*, and some of the others are capable of inflicting painful and often erythematous lesions.

Many scorpion venoms contain low-molecular-weight proteins, peptides, amino acids, nucleotides, and salts, among other components (Possani et al., 2000; Goldin, 2001; Rodriguez de la Vega and Possani, 2004, 2005). The neurotoxic fractions are generally classified on the basis of their molecular size. The short-chain toxins with 20 to 40 amino acid residues have three or four disulfide bonds and appear to affect potassium or chloride channels. The long-chain toxins have 58 to 76 amino acid residues (6500 to 8500 Da) with four disulfide bonds and affect mainly the sodium channels (Mouhat et al., 2004). These particular toxins may have an effect on other voltage-dependent channels. The amino acid content is known for more than 90 species, and there appears to be a high number of cysteine residues in most of these venoms. The toxins can selectively bind to a specific channel of excitable cells, thus impairing the initial depolarization of the action potential in the nerve and muscle that results in their neurotoxicity. It appears that the way some scorpion venoms differently affect mammalian, as opposed to insect tissues, is related to the structural basis of the gates in the two organisms. Not all scorpions, however, have fractions that affect neuromuscular transmission. In fact, Rodriguez de la Vega and Possani (2005) constructed a phylogenetic tree using 191 different amino acid sequences from long-chain peptides and discussed their functional divergence and extant biodiversity. The effects of scorpion venom on various potassium channels have been reviewed (Rodriguez de la Vega and Possani, 2004).

The symptoms and signs of scorpion envenomation differ considerably depending on the species (Russell, 2001). Common offenders are members of the family Vejovidae, generally found in the southwestern and western United States, Central America, and South America. Their sting gives rise to localized pain, swelling, tenderness, and mild parasthesia. Systemic reactions are rare, although weakness, fever, and muscle fasciculations have been reported.

Envenomations by some members of the genus *Centruroides* are clinically the most important, particularly in the western United States. The bark scorpion, *C. exilicauda*, is often found hiding under the loose bark of trees or in dead trees or logs, and may frequent human dwellings. Straw to yellowish-brown or reddish-brown in color, it is often easily distinguishable from other scorpions in the same habitat by its long, thin telson, or tail, and its thin pedipalps, or pincer-like claws. In children, their sting may produce initial pain, although some children do not complain of pain and are unaware of the injury. The area becomes sensitive to touch, and merely pressing lightly over the injury will elicit an immediate retraction. Usually there is little or no local swelling and only mild erythema. The child becomes tense and restless and shows abnormal and random head and neck movements. Often the child will display roving eye movements. *Centruroides vittatus*, the striped bark scorpion (Fig. 26-21), is commonly involved in envenomenation but fatalities are rare. In their review of *Centruroides sculpturatus* stings, Rimsza et al. (1980) noted visual signs, including nystagmus roving eye and oculogyric movements, in 12 of 24 patients stung by this scorpion. Tachycardia is usually evident within 45 minutes as well as some hypertension. Although this is not seen in children as early or as severely as in adults, it is often present within an hour following the sting. Respiratory and heart rates are increased, and by 90 minutes the child may appear quite ill. Fasciculations may be seen over the face or large muscle masses, and the child may complain of generalized weakness and display some ataxia or motor weakness. Opisthotonos is not uncommon. The respiratory distress may proceed to respiratory paralysis. Excessive salivation is often present and may further impair respiratory function. Slurring of speech may

Table 26-10

Location of Some Medically Important Scorpions

GENUS	DISTRIBUTION
Androctonus species	North Africa, Middle East, Turkey
Buthus species	France and Spain to Middle East and north Africa, Mongolia, China
Buthotus species	Africa, Middle East, central Asia
Centruroides species	North, Central, South America
Heterometrus species	Central and Southeast Asia
Leiurus species	North Africa, Middle East, Turkey
Mesobuthus species	Turkey, India
Parabuthus species	Southern Africa
Tityus species	Central and South America

Figure 26-21. *Centruroides vittatus (striped bark scorpion).*

be present, and convulsions may occur. If death does not occur, the child usually becomes asymptomatic within 36 to 48 hours.

In adults, the clinical picture is somewhat similar, but there are some differences (Russell, 2001). Almost all adults complain of immediate pain after the sting, regardless of the *Centruroides* species involved. Adults do not show the restlessness that is seen in children. Instead, they are tense and anxious. They develop tachycardia and hypertension, and respirations are increased. They may complain of difficulties in focusing and swallowing. In some cases, there is some general weakness and pain on moving the injured extremity. Convulsions are very rare, but ataxia and muscle incoordination may occur. Most adults are asymptomatic within 12 hours, but may complain of generalized weakness for 24 hours or more.

Spiders

Of the 30,000 or so species, at least 200 have been implicated in significant bites on humans. Spiders are predaceous, polyphagous arachnids that generally feed on insects or other arthropods. Additional information on spider bites can be found elsewhere (Gertsch, 1979; Maretiĉ and Lebez, 1979; Russell, 2001). Table 26-11 provides a short list of spiders with their associated toxins and the targets of their toxins.

All spiders except the Uloboridae family possess a venom apparatus that produces neurotoxins designed to paralyze or kill prey. Spider venoms are complex mixtures of low-molecular-weight components, including inorganic ions and salts, free acids, amino acids, biogenic amines and neurotransmitters, and polypeptide toxins. The acylpolyamines, composed of a hydrophobic aromatic carboxylic acid linked to a lateral chain of one to nine aminopropyl, aminobutyl, or aminopentyl units, are voltage-dependent open-channel blockers (sodium, calcium, and potassium channels) and/or blockers of the ion channel associated with glutamate receptors. They also act on nicotinic acetylcholine receptors. The acylpolyamines possess insecticidal activity and induce fast insect paralysis via a reversible block of the insect neuromuscular junction. Polypeptide toxins include the ion channel blockers, pore-forming peptides, and enzymes. In particular, hanatoxins 1 and 2 have allowed characterization of voltage-dependent potassium channels (Swartz and MacKinnon, 1995; Yellen, 2002). The ω-agatoxins block voltage-sensitive vertebrate calcium channels (Corzo and Escoubas, 2003). The ω-atracotoxins have greater selectivity on insect voltage-sensitive calcium channels (Wang et al., 2001). Many more spiders and the spider peptide toxins have been studied to date (Fatehi et al., 1997; Liu et al., 1997; Corzo and Escoubas, 2003; Adams, 2004; Kuhn-Nentwig et al., 2004; Rodriguez de la Vega and Possani, 2004; Ushkaryov et al., 2004; Wilson and Alewood, 2006). The small spider peptide toxins are relatively easy to produce by chemical synthesis or by recombinant means. Peptide toxins from spiders have proved useful in discriminating between different cellular components of native ion channel currents and for the molecular isolation and designation of cellular receptors (Escoubas et al., 2000; Corzo and Escoubas, 2003; Adams, 2004).

Poor case definition and spider identification contribute to the controversy regarding the clinical consequences and inappropriate diagnosis of spider bites worldwide. Many patients never see the spider, yet many skin lesions or areas of necrosis are attributed to spider bites. The medically important spiders include the *Agelenopsis* sp., *Latrodectus* sp., *Loxosceles* sp., *Atrax* sp., *Hadronyche* sp., and *Phoneutria* sp. Table 26-12, summarized from Isbister and White (2004), lists local and systemic effects for known cases of major spider groups in Australia.

Table 26-11

Some Significant Spiders, Their Toxins, and the Targets of the Toxins

SPIDER	PEPTIDE	TARGET
Acanthoscurria gomesiana	Gomesin	PLM
Agelenopsis aperta	ω-AfaI-IVA μ-Afatoxin 1-6	Ca^{2+} Na^{+}
Grammostola spatula	HaTx1,2 GsMTx2,4 GSTxSIA	K^{+} MS Ca^{2+}
Hadronyche versuta	ω-ACTX-Hv1a ω-ACTX-Hv2a δ-ACTX-Hv1a	Ca^{2+} Ca^{2+} Na^{+}
Heteroscodra maculate	HmTx1,2	K^{+}
Ornithoctonus huwena	Huwentoxin I Huwentoxin IV	Ca^{2+} Na^{+}
Psalmopoeus cambridgei	PcTx1	ASIC
Phrixotrichus auratus	PaTx1,2	K^{+}
Thrixopelma pruriens	ProTxI,II	Na^{+}

Abbreviations: ASIC, acid-sensing ion channels; $Ca2^{+}$, K^{+}, and Na^{+}, calcium, potassium, and sodium ion channels; MS, mechanosensitive ion channels; PLM, phospholipid membranes.

Additional species, their toxins, and their targets may be obtained from the article by Corzo and Escoubas (2003).

Agelenopsis Species (American Funnel Web Spiders)

The American funnel web spider (*Agelenopsis aperta*) contains three classes of agatoxins that target ion channels (Adams, 2004). The α-agatoxins appear to be use-dependent, noncompetitive antagonists of the glutamate receptor channels. These are low-molecular-weight acylpolyamines that are devoid of amino acids. Mass spectrometry analysis has identified more than 33 α-agatoxins in *A. aperta* venom (Chesnov et al., 2001). The μ-agatoxins are 36 to 37 amino acid, C-terminal amidated, peptides with four internal disulfide bridges (Skinner et al., 1989). These μ-agatoxins cause increased spontaneous release of neurotransmitter from presynaptic terminals and repetitive action potentials in motor neurons. In addition, the μ-agatoxins are specific for insect sodium channels. The ω-amatoxins are a structurally diverse group of peptides that are selective for voltage-activated calcium channels. There are four types of ω-amatoxins that can be distinguished by sequence similarity and their spectrum of action against insect and vertebrate calcium channels. The μ-agatoxins causing channels to open at the normal resting potentials synergize the action of the α-agatoxins. It is interesting to note that the agatoxins are used as selective pharmacologic probes to characterize ion channels in organs such as brain and heart, and have been evaluated as candidate biopesticides.

Latrodectus Species (Widow Spiders)

Found throughout the world in all continents with temperate or tropical climates, these spiders are commonly known as the black widow, brown widow, or red-legged spider. They, however, have many other common names in English: hourglass, poison lady, deadly spider, red-bottom spider, T-spider, gray lady spider, and shoe-button spider. Although both male and female widow spiders are venomous, only the female has fangs that are large and strong enough to penetrate the human skin. Mature *Latrodectus mactans* females range in body length from

Table 26-12

Comparison of Clinical Effects of Bites by Some Spiders of Australia

CLINICAL EFFECTS	*LACTRODECTUS* REDBACK SPIDERS	*STEATODA* CUPBOARD SPIDERS	LAMPONIDAE WHITE-TAIL SPIDERS	MYGALOMORPHAE FUNNEL WEB SPIDERS, MOUSE SPIDERS, TRAPDOOR SPIDERS
Severe pain (%)	62	26	27	49
Duration of pain	36 hours	6 hours	0.8 hours	1 hour
Fang marks (%)	6	17	17	58
Initial erythema	74	96	83	36
Swelling (%)	7	9	8	13
Itchiness (%)	38	48	44	0
Nausea, vomiting, headache, malaise (%)	35	30	9	36
Distal limb bite (%)	46	52	82	91

Figure 26-22. *Latrodectus mactans (female black widow spider).*

10 to 18 mm, whereas males range from 3 to 5 mm (Fig. 26-22). These spiders have a globose abdomen varying in color from gray to brown to black, depending on the species. In the black widow, the abdomen is shiny black with a red hourglass or red spots and sometimes with white spots on the venter (Russell, 2001).

The latrotoxins, a family of high-molecular-weight proteins that are found in *Latrodectus* venoms, target different classes of animals including vertebrates, insects, and crustaceans (Grishin, 1998, 1999; Ushkaryov et al., 2004). The toxins are synthesized as large precursors containing around 1000 amino acid residues (around 132 to 156 kDa) that undergo proteolytic processing to 110 to 130 kDa and activation in the lumen of the venom gland. Mature latrotoxins are structurally conserved and contain multiple ankyrin repeats. At least seven different latrotoxins have been isolated and all are large acidic proteins (pI approximately 5.0 to 6.0). Some are called latroinsectotoxins because they affect insects but not vertebrates, and one protein called α-latrocrustatoxin is active only in crayfish. All latrotoxins stimulate massive release of neurotransmitters after binding to specific neuronal receptors.

α-Latrotoxin is the most studied protein that is toxic only to vertebrates and not to insects or crustaceans (Ushkaryov et al., 2004). A presynaptic toxin is said to exert its toxic effects on the vertebrate central nervous system depolarizing neurons by increasing intracellular [Ca^{2+}] and by stimulating exocytosis of neurotransmitters from nerve terminals (Holz and Habener, 1998). The purported three-dimensional structure of α-latrotoxin consists of tetrameric complexes with a central channel that inserts into the lipid bilayer. A G protein–coupled receptor latrophilin and a single-transmembrane receptor neurenin are high-affinity binding sites for α-latrotoxin (Ushkaryov et al., 2004). The latrotoxins act by both calcium-dependent and calcium-independent mechanisms. In fact, a mutant recombinant α-latrotoxin that does not form pores has been invaluable in furthering our understanding of the multiple actions of the toxin (Volynski et al., 2003). α-Latrotoxin and its mutants are versatile tools for the study of exocytosis. In particular, studies with this toxin have helped confirm the vesicular hypothesis of transmitter release (Hurlbut et al., 1990), establish the requirement of calcium ion for endocytosis (Ceccarelli and Hurlbut, 1980), characterize individual neurotransmitter sites in the central nervous system (Auger and Marty, 1997), and identify two families of important neuronal cell surface receptors (Krasnoperov et al., 1997).

Bites by the black widow are described as sharp and pinprick-like, followed by a dull, occasionally numbing pain in the affected extremity and by pain and cramps in one or several of the large muscle masses (Russell, 2001). Rarely is there any local skin reaction except during the first 60 minutes following the bite. Muscle fasciculations frequently can be seen within 30 minutes of the bite. Sweating is common, and the patient may complain of weakness and pain in the regional lymph nodes, which are often tender on palpation and occasionally are enlarged; lymphadenitis is frequently observed. Pain in the low back, thighs, or abdomen is a common complaint, and rigidity of the abdominal muscles is seen in most cases in which envenomation has been severe. Severe paroxysmal muscle cramps may occur, and arthralgia has been reported. Hypertension is a common finding, particularly in the elderly after moderate to severe envenomations. Blood studies are usually normal.

***Loxosceles* Species (Brown or Violin Spiders)** These primitive spiders are variously known in North America as the fiddleback spider or the brown recluse (Fig. 26-23). There are over 100 species of *Loxosceles*. The abdomen of these spiders varies in

Figure 26-23. *Loxosceles reclusa (male brown recluse spider) with the violin pattern on the dorsal cephalothorax.*

color from grayish to orange and reddish-brown to blackish and is distinct from the pale yellow to reddish-brown background of the cephalothorax. This spider has six eyes grouped in three dyads. Females average 8 to 12 mm in body length, whereas males average 6 to 10 mm. Both males and females are venomous (Russell, 2001).

The venom of *Loxosceles* spiders appears to contain phospholipase, protease, esterase, collagenase, hyaluronidase, deoxyribonuclease, ribonuclease, dipeptides, dermonecrosis factors, and sphingomyelinase D. The venom has coagulation and vasoconstriction properties and it causes selective vascular endothelial damage. There are adhesions of neutrophils to the capillary wall with sequestration and activation of passing neutrophils by the perturbed endothelial cells (Patel et al., 1994). In *Loxosceles intermedia*, the toxic effects appear to be associated with a 35-kDa protein that demonstrates a complement-dependent hemolytic activity and a dermonecrotic-inducing factor. ^{31}P-nuclear magnetic resonance assay of the four bands representing proteins, measuring 34 kDa in the venom, produced three proteins with sphingomyelinase D activity (Merchant et al., 1998). An endotoxemic-like shock, showing eosinophilic material in the proximal and distal tubules and tubular necrosis, was the most common histopathological finding, preceded in mice by prostration, acute cachexia, hypothermia, neurological changes, and hemoglobinuria (Tambourgi et al., 1998).

The bite of this spider produces about the same degree of pain as does the sting of an ant, but sometimes the patient may be unaware of the bite. In most cases, a local burning sensation, which may last for 30 to 60 minutes, develops around the injury. Pruritus over the area often occurs, and the area becomes red, with a small blanched area surrounding the reddened bite site. Skin temperature usually is elevated over the lesion area. With significant envenomations, the reddened area enlarges and becomes purplish during the subsequent 1 to 8 hours. It often becomes irregular in shape, and as time passes, hemorrhages may develop throughout the area. A small bleb or vesicle may form at the bite site, increase in size, and rupture with subsequent pustule formation. The red hemorrhagic area continues to enlarge, as does the pustule. The whole area may become swollen and painful, and lymphadenopathy is common. During the early stages, the lesion often takes on a bull's-eye appearance, with a central white vesicle surrounded by the reddened area and ringed by a whitish or bluish border. The central pustule ruptures, and necrosis to various depths can be visualized (Russell, 2001).

In serious bites, the lesion can measure 8 × 10 cm^2 with severe necrosis invading muscle tissue. On the face, large lesions resulting in extensive tissue destruction and requiring subsequent plastic surgery sometimes are seen after bites by *Loxosceles laeta* in South America. Systemic symptoms and signs include fever, malaise, stomach cramps, nausea and vomiting, jaundice, spleen enlargement, hemolysis, hematuria, and thrombocytopenia. Fatal cases, while rare, usually are preceded by intravascular hemolysis, hemolytic anemia, thrombocytopenia, hemoglobinuria, and renal failure (Russell, 2001).

***Steatoda* Species** These spiders are variously known as the false black widow, combfooted, cobweb, or cupboard spiders. The female of *Steatoda grossa* differs from *L. mactans* and *Latrodectus hesperus* in having a purplish-brown abdomen rather than a black one. It is less shiny, and its abdomen is more oval than round. It may have pale yellow or whitish markings on the dorsum of the abdomen, and no markings on the venter. The abdomen of some species is orange, brown, or chestnut in color, and often bears a light band across the anterior dorsum (Russell, 2001).

The venom of *Steatoda paykulliana* stimulates the release of transmitter substances similar to *Latrodectus* venom (Cavalieri et al., 1987). The venom is said to form ionic channels permeable for bivalent and monovalent cations, and the duration of time in the open state depends on the membrane potential (Sokolov et al., 1984). *S. paykulliana* venom induces strong motor unrest, clonic cramps, exhaustion, ataxia, and then paralysis in guinea pigs. Bites by *S. grossa* or *Steatoda fulva* in the United States have been followed by local pain, often severe; induration; pruritus; and the occasional breakdown of tissue at the bite site (Russell, 2001).

***Cheiracanthium* Species (Running Spiders)** The 160 species of this genus have an almost circumglobal distribution, although only four or five species have been implicated in bites on humans (Russell, 2001). *Cheiracanthium punctorium*, *Cheiracanthium inclusum*, *Cheiracanthium mildei*, *Cheiracanthium diversum*, and *Cheiracanthium japonicum* are often implicated in envenomations. The abdomen is convex and egg shaped and varies in color from yellow, green, or greenish-white to reddish-brown; the cephalothorax is usually slightly darker than the abdomen. The chelicerae are strong, and the legs are long, hairy, and delicate. The spider ranges in length from 7 to 16 mm. Like *Phidippus* jumping spiders but even more so, *Cheiracanthium* tends to be tenacious and sometimes must be removed from the bite area. For that reason, there is a high degree of identification following the bite of these spiders. The most toxic venom fraction is said to be a protein of 60 kDa, and the venom is high in norepinephrine and serotonin.

The patient usually describes the bite by *C. inclusum* as sharp and painful, with the pain increasing during the first 30 to 45 hours. The patient complains of dull pain over the injured part. A reddened wheal with a hyperemic border develops. Small petechiae may appear near the center of the wheal. Skin temperature over the lesion is often elevated, but body temperature is usually normal. Lymphadenitis and lymphadenopathy may develop. *C. japonicum* produces more severe manifestations, including severe local pain, nausea and vomiting, headache, chest discomfort, severe pruritus, and shock (Russell, 2001).

***Theraphosidae* Species (Tarantulas)** True tarantulas are members of the family Theraphosidae and there are around 800 species that are distributed worldwide, but especially in tropical or semitropical regions. Tarantulas are predators and they feed on various vertebrate and invertebrate preys that are captured after envenomation with venoms that act rapidly and irreversibly on the central and peripheral nervous systems. In humans, reported bites elicit mild to severe local pain, strong itching, and tenderness that may last for several hours. Edema, erythema, joint stiffness, swollen limbs, burning feelings, and cramps are common. In more

severe cases, strong cramps and muscular spasms lasting up to several hours may be observed. *Poecilotheria* and *Stromatopelma* spp. appear to be most toxic to humans, although no fatalities have been reported (Escoubas and Rash, 2004).

Tarantula venoms have been extensively studied, and modern purification often uses orthogonal HPLC separations that combine reversed-phase and ion-exchange chromatography. Most spider peptide toxins appear to have basic pI in the 9 to 11 range (Escoubas et al., 2000). At least 33 peptide toxins have been described from various tarantula venoms. These have a molecular weight of 3000 to 5700 Da, and targets include voltage-gated potassium, sodium, and calcium channels, tetrodotoxin-sensitive channels, and acid-sensing ion channels, which are sensitive to extracellular pH (reviewed by Escoubas and Rash, 2004). At least two distinct structural motifs have been characterized: the inhibitory cystine knot (ICK) with a consensus sequence of C_IX_{3-7}–$C_{II}X_{3-8}$–$C_{III}X_{0-7}$–$C_{IV}X_{1-4}$–C_VX_{4-13}–C_{VI} and disulfide bond pairing of C_I–C_{IV}, C_{II}–C_V, and C_{III}–C_{VI} (Craik et al., 2001), and the disulfide-directed β-hairpin (DDH) motif that comprises an antiparallel β-hairpin stabilized by two disulfide bridges (Wang et al., 2000). Tarantula toxins have been classified as long-loop ICK, short-loop ICK, or DDH toxins (Escoubas and Rash, 2004).

Theraphosid spiders contain several toxins that are being evaluated for development as antiarrhythmic or as antinociceptive drugs. In particular, *Grammostola* mechanotoxin 4 from *Grammostola spatulata* has considerable promise as an antiarrhythmic. Protoxin I and II from *Thrixopelma pruriens* have promise as analgesics because they inhibit the tetrodotoxin-resistant sodium channels (Middleton et al., 2002).

Future work on the toxins of tarantulas will encompass genomic and proteomic approaches. Expanding knowledge suggests trends in the association of primary and three-dimensional structures with pharmacologic activity. Continued improvement in isolation and purification technologies plus the combination of cDNA library screening with mass spectrometry will prove invaluable in characterization of toxin function and definition of toxin targets.

Ticks

Many of the approximately 900 species of ticks are associated with disease in humans and wild and domesticated animals (Rash and Hodgson, 2002; Barker and Murrell, 2004; Steen et al., 2006). The saliva of certain ticks of the families Ixodidae, Argasidae, and Nuttalliellidae causes tick paralysis. The tick bite involves insertion of cutting, tube-like mouthparts through the host's skin with anchoring so that the tick can feed for hours, days, or weeks. Saliva from the salivarium flows outward initially and the blood meal flows inward afterward. Ticks are known to transmit the organisms causing Lyme disease, Rocky Mountain spotted fever, babesiosis, leptospirosis, Q fever, ehrlichiosis, typhus, tick-borne encephalitis, and others. In fact, the import of immunosuppression by tick saliva in the transmission of flaviviruses has been discussed (Nuttall and Labuda, 2003).

Tick saliva contains a number of active constituents (Steen et al., 2006). For example, saliva from *Ixodes scapularis* contains apyrase (ATP diphosphohydrolase), which hydrolyzes ADP that is released at the bite site thereby inhibiting ADP-induced platelet aggregation (Mans et al., 1998); kininase (ACE-like protein or angiotensin-converting enzyme-like protein), which hydrolyzes circulating kinins and reduces the host inflammatory response (Francischetti et al., 2003); glutathione peroxidase (Das et al., 2001); serine protease inhibitors, which inhibit coagulation enzymes (Valenzuela, 2004); an anticomplement protein that inhibits an enzyme in the alternative pathway for complement (Valenzuela et al., 2000); an amine-binding protein that binds serotonin, histamine, and other biogenic amines (Sangamnetdej et al., 2002); and prostanoids (PGE_2 and $PGF_{2\alpha}$) (Inokuma et al., 1994). A discussion of toxins from other species may be found elsewhere (Cavassani et al., 2005; Steen et al., 2006).

Potentially 50 species of ticks are associated with clinical paralysis (Russell, 2001). As tick bites are often not felt, the first evidence of envenomation may not appear until several days later, when small macules 3 to 4 mm in diameter develop that are surrounded by erythema and swelling, often displaying a hyperemic halo. The patient often complains of difficulty with gait, followed by paresis and eventually locomotor paresis and paralysis. Problems in speech and respiration may ensue and lead to respiratory paralysis if the tick is not removed. The saliva of *Ixodes holocyclus* has yielded a peptide holocyclotoxin-1 that may cause paralysis (Masina and Broady, 1999). Peak paralytic activity was found between 60 and 100 kDa, and was a trimer of a neurotoxic protein subunit of 23 kDa (Crause et al., 1993). Symptoms resolve rapidly on removal of the tick (Russell, 2001).

CHILOPODA (CENTIPEDES)

These elongated, many-segmented brownish-yellow arthropods have a pair of walking legs on most segments, and they are fast moving, secretive, and nocturnal and are found worldwide. They feed on other arthropods and even small vertebrates and birds. The first pair of legs behind the head is modified into poison jaws. Centipedes range in length from 3 to almost 300 mm. In the United States, the prevalent biting genus is a *Scolopendra* species. The venom is concentrated within the intracellular granules, discharged into vacuoles of the cytoplasm of the secretory cells, and moved by exocytosis into the lumen of the gland; from thence ducts carry the venom to the jaws (Ménez et al., 1990).

Centipede venoms contain high-molecular-weight proteins, proteinases, esterases, 5-hydroxytryptamine, histamine, lipids, and polysaccharides (Mebs, 2002). Such venom contains a heat-labile cardiotoxic protein of 60 kDa that produces, in humans, changes associated with acetylcholine release (Gomes et al., 1983). The bite produces two tiny punctures, sharp pain, immediate bleeding, redness, and swelling often lasting for 24 hours. Localized tissue changes and necrosis have been reported, and severe envenomations may cause nausea and vomiting, changes in heart rate, vertigo, and headache. In the most severe cases, there can be mental disturbances (Bush et al., 2001; Russell, 2001; Mebs, 2002).

DIPLOPODA (MILLIPEDES)

Ranging in length from 20 to 300 mm, these arthropods are cylindrical, worm-like creatures, mahogany to dark brown or black in color, and bearing two pairs of jointed legs per segment. In Australia and New Guinea particularly, the repellent secretions expelled from the sides of their bodies contain a toxin of benzoquinone derivatives plus a variety of complex substances such as iodine and hydrocyanic acid, which the animal makes use of to produce hydrogen cyanide (Kuwahara et al., 2002). Some species can spray these defensive secretions, and eye injuries are not uncommon. The lesions produced by millipedes consist of a burning or prickling sensation and development of a yellowish or brown-purple lesion; subsequently, a blister containing serosanguinous fluid forms, which may rupture. Eye contact can cause acute conjunctivitis, periorbital edema, keratosis, and much pain; such an injury must be treated immediately (Russell, 2001).

INSECTA

Heteroptera (True Bugs)

The clinically most important of the true bugs are the Reduviidae (the reduviids): the kissing bug, assassin bug, wheel bug, or cone-nose bug of the genus *Triatoma* (Russell, 2001). Generally, they are parasites of rodents and common in the nests of wood rats or in wood piles. These are elongated bugs with freely movable, cone-shaped heads, and straight beaks. The most commonly involved species appear to be *Triatoma protracta*, *Triatoma rubida*, *Triatoma magista*, *Reduvius personatus*, and *Arilus cristatus*. The average length of these bugs is 19 mm. The venom of these bugs appears to have apyrase activity and to lack 5-nucleotidase, inorganic pyrophosphatase, phosphatase, and adenylate kinase activities, but it is fairly rich in protease properties. It inhibits collagen-induced platelet aggregation. Three peptides isolated from the saliva of predatory reduviids are 34 to 36 amino acid residues in size, are calcium channel blockers similar to ω-conotoxins, and belong to the four-loop disulfide bridge scaffold structural class (Corzo et al., 2001). The bites of *Triatoma* species are painful and give rise to erythema, pruritus, increased temperature in the bitten part, localized swelling, and—in those allergic to the saliva—systemic reactions such as nausea and vomiting and angioedema. With some bites the wound area will slough, leaving a depression.

The water-dwelling true bugs are of at least three families, Naucoridae, Belostomatidae, and Notonectidae, which are capable of biting and envenomating humans (Russell, 2001). They are found in lakes, ponds, marshes, quiet fresh water, and swimming pools. *Lethocerus americanus*, a Belostomatidae, ranges in length from 12 to 70 mm, but some water bugs may reach 150 mm. The dorsal side is usually tan or brown, but it may be brightly colored, while the ventral side is brown. They are very strong insects and can immobilize snails, tadpoles, salamanders, and even small fish and water snakes. Water bug saliva is said to contain digestive enzymes, neurotoxic components, and hemolytic fractions. ApoLp-III isolated from the hemolymph of *Lathocerus medius* is about 19 kDa and has an amino acid composition high in methionine. If molested, water bugs will bite, and their bites give rise to immediate pain, some localized swelling, and possibly induration and formation of a small papule.

Hymenoptera (Ants, Bees, Wasps, and Hornets)

Formicidae (Ants) Most ant species sink their powerful mandibles into the flesh, providing leverage, and then drive their stings into the victim. Most ants have stings, but those that lack them can spray a defensive secretion from the tip of the gaster, which is often placed in the wound of the bite. Ants of the different species vary considerably in length, ranging from less than 1.5 to over 35 mm. Clinically important stinging ants are the harvesting ants (*Pagonomyrmex*), fire ants (*Solenopsis*), and little fire ants (*Ochetomyrmex*). The harvester ants are large red, dark brown, or black ranging in size from 6 to 10 mm and having fringes of long hairs on the posterior of their heads (Russell, 2001).

The venoms of the ants vary considerably. The venoms of the Ponerinae, Ecitoninae, and *Pseudomyrmex* are proteinaceous in character. The Myrmicinae venoms are a mixture of amines, enzymes, and proteinaceous materials, histamine, hyaluronidase, phospholipase A, and hemolysins, which hemolyze erythrocytes and mast cells. Formicinae ant venom contains about 60% formic acid. Fire ant venoms are poor in polypeptides and proteins, but are rich in alkaloids such as solenopsin (Russell, 2001; Mebs, 2002). The sting of the fire ant gives rise to a painful burning sensation, after which a wheal and localized erythema develop, leading in a few hours to a clear vesicle. Within 12 to 24 hours, the fluid becomes purulent and the lesion turns into a pustule. It may break down or become a crust or fibrotic nodule. In multiple stings, there may be nausea, vomiting, vertigo, increased perspiration, respiratory difficulties, cyanosis, coma, and even death. Cross-exposure to the venom of other species of ants is possible. Allergic reactions and fatal anaphylactic shock are seen in sensitized victims (Hoffman, 2006). Treatment of ant stings is dependent on the number of bites, on whether an allergic reaction is involved, and on whether there are possible complications.

Apidae (Bees) This family includes the bumble bees, honeybees, carpenter bees, and yellow jackets. The commonest stinging bees are *Apis mellifera* and the Africanized bee, *Apis mellifera adansonii*, and the incidence of Hymenoptera poisonings is increasing. The venom of the Africanized bee is not remarkably different from that of the European bee, *A. m. mellifer* (Fig. 26-24). The former bee is smaller and gives less venom, but its aggressiveness is such that attacks of 50 to hundreds of bees are not unusual (Russell, 2001).

The venom contains biologically active peptides, such as melittin, apamine, mast cell–degranulating peptide, and others, as well as phospholipases A_2 and B, hyaluronidase, histamine, dopamine, monosaccharides, and lipids (Mebs, 2002). Melittin, which is secreted as the 70 amino acid prepromelittin, consists of 26 amino acids with no cysteines that have natural detergent-like properties and causes erythrocyte lysis. Melittin also forms tetramers with pores, thereby facilitating ion transport through membranes. In particular, melittin tetramers cause a breakdown of the resting potential and rapid depolarization of nociceptors, which induces pain (Demsey, 1990; Bechinger, 1997). The compound apamine contains 18 amino acids cross-linked by two disulfide bridges. Apamine is a blocker of calcium-dependent potassium channels and is thought to be the "lethal factor" (Habermann, 1984). In addition to apamine, mast cell–degranulating peptide is also a basic peptide containing 22 amino acids with two disulfide bonds. Besides stimulating release of histamine, this peptide specifically inhibits voltage-dependent potassium channels (Dreyer, 1990; Baku, 1999).

Bee stings typically produce immediate, sharp or burning pain, slight local erythema, and edema followed by itching. The edema may vary depending on location of the sting. It is said that 50 stings can be serious and lead to respiratory dysfunction, intravascular hemolysis, hypertension, myocardial damage, hepatic changes, shock, and renal failure. With 100 or more stings, death can occur. In patients who are allergic to bee stings, immediate allergic reaction with the risk of anaphylactic shock requires urgent medical treatment (Mebs, 2002; Hoffman, 2006).

Figure 26-24. *Apis mellifera mellifera (honey bee).*

Vespidae (Wasps) This family includes wasps and hornets. These venoms contain a high content of peptides, which include mastoparan in wasps and hornets and crabolin from hornet venom. These peptides release histamine from mast cells and consist of 13 to 17 amino acids with no disulfide bridges. Other peptides named wasp kinins cause immediate pain, vasodilation, and increased vascular permeability leading to edema. These venoms also contain phospholipases and hyaluronidases, which contribute to the breakdown of membranes and connective tissue to facilitate diffusion of the venom. These proteins also contribute to the allergenicity of the venoms (Mebs, 2002; Hoffman, 2006).

Lepidoptera (Caterpillars, Moths, and Butterflies)

The urticating hairs, or setae, of caterpillars are effective defensive weapons that protect some species from predators. The setae are attached to unicellular poison glands at the base of each hair. Both the larvae and the adults are capable of stinging, either by direct contact with the setae or indirectly when the creature becomes irritated. It appears that contraction of the caterpillar's abdominal muscles is sufficient to release the barbs from their sockets, allowing them to become airborne. The toxic material found in the venom glands contains aristolochic acids, cardenolides, kallikrein, and histamine among other substances. Fibrinolytic activity has been found in 16 and 18 kDa components (isoelectric point of 8.5); coagulation defects such as prolonged prothrombin and partial thromboplastin times have been detected, and decreases in fibrinogen and plasminogen have been noted. It is thought that the hemorrhagic syndrome cannot be classified as being either totally fibrinolytic or a syndrome such as disseminated intravascular coagulopathy. The spicules of *Thaumetopoea pityocampa* contain a 28-kDa toxin called thaumetopoein, which is a strong dermal irritant and highly allergenic peptide (Kawamoto and Kumada, 1984; Russell, 2001; Mebs, 2002).

In some parts of the world, the stings of several species of Lepidoptera give rise to a bleeding diathesis, often severe and sometimes fatal. Envenomation by members of the family Saturniidae, the buck moths, the grapeleaf skeletonizer (family Zygaenidae), the puss moth (family Megalopygidae), and the brown-tailed moth (*Euproctis* species) generally gives rise to little more than immediate localized itching and pain, usually described as burning, followed in some cases by urticaria, edema, and occasionally fever. The hemolymph and spicules contain highly active clotting enzymes, a protease with fibrinolytic activity and an enzyme that activates prothrombin. In the more severe cases—often due to *Megalopyge*, Dioptidae, *Automeris*, and *Hemileuca* spp.—there is localized pain as well as papules (sometimes hemorrhagic) and hematomas; on occasions there may also be headache, nausea, vomiting, hematuria, lymphadenitis, and lymphadenopathy. Contacts with larvae of the saturnid moths in South America (*Lonomia acheolus* and *Lonomia oblique*, Fig. 26-25) can cause severe coagulopathy, due to inhibition of clotting factor XIII by a venom component called lonomine V. Severe envenomation can cause cerebral hemorrhage and death (Guerrero et al., 1999).

Figure 26-25. *Lonomia oblique (giant silkworm moth).*

Figure 26-26. *Conus geographus (geography cone).*

MOLLUSCA (CONE SNAILS)

Human interest in this group of mollusks has been due to the beautiful patterns on their shells. Cone snails were known to Roman scholars and natural history collectors, as the shells were often made into jewelry. The first record of fatality from cone snail sting may be found in the book of Rumphius from 1705. The genus *Conus* is a group of approximately 500 species of carnivorous predators found in marine habitats that use venom as a weapon for prey capture (Fig. 26-26). Cone snails have a venom duct for synthesis and storage of venom and hollow harpoon-like teeth for injection of the venom (Rockel et al., 1995).

Cone snails may be divided into three groups depending on preferred prey. The largest group contains worm-hunting species that feed on polychaetes (segmented marine worms in the phylum Annelida). The second group is molluscivorous and hunts other gastropods. The final group is piscivorous and has venoms that rapidly immobilize fish (Olivera, 1997, 2002; Mebs and Kauferstein, 2005).

There are probably over 100 different venom components per species (Terlau and Olivera, 2004). Components have become known as conotoxins, which may be rich in disulfide bonds, and conopeptides. Molecular targets include G protein–coupled receptors, neurotransmitter transporters, and ligand- or voltage-gated ion channels. Some components have enzymatic activity.

Fig. 26-27 provides an overview of peptidic *Conus* venom components, indicating gene superfamilies, disulfide bond characteristics, and general targets (McIntosh et al., 1999; Olivera, 2002). The two major divisions of *Conus* toxins are the disulfide-rich conotoxins and the peptides that lack multiple disulfide cross-links. The arrangement of cysteines in the primary sequence is restricted to only a few patterns, which may be diagnostic of the gene superfamily. Most disulfide-rich conotoxins are small and consist of 12 to 30 amino acids. These toxins contain an unusually diverse complement of posttranslationally modified amino acids, including hydroxyproline, *O*-glycosylated serine or threonine, γ-carboxyl-glutamate, sulfated tyrosine, and D-amino acids (Craig et al., 1999). Apparently, the posttranslational modification enzyme γ-carboxylase is present in their venom ducts (Bandyopadhyay et al., 2002). The enzyme has a recognition signal in the pro region of the precursor that instructs the enzyme to modify specific amino acid residues in the mature toxin region. Thus, the pro region of conopeptide precursors provides potential anchor-binding sites for posttranslational modification enzymes (Hooper et al., 2000).

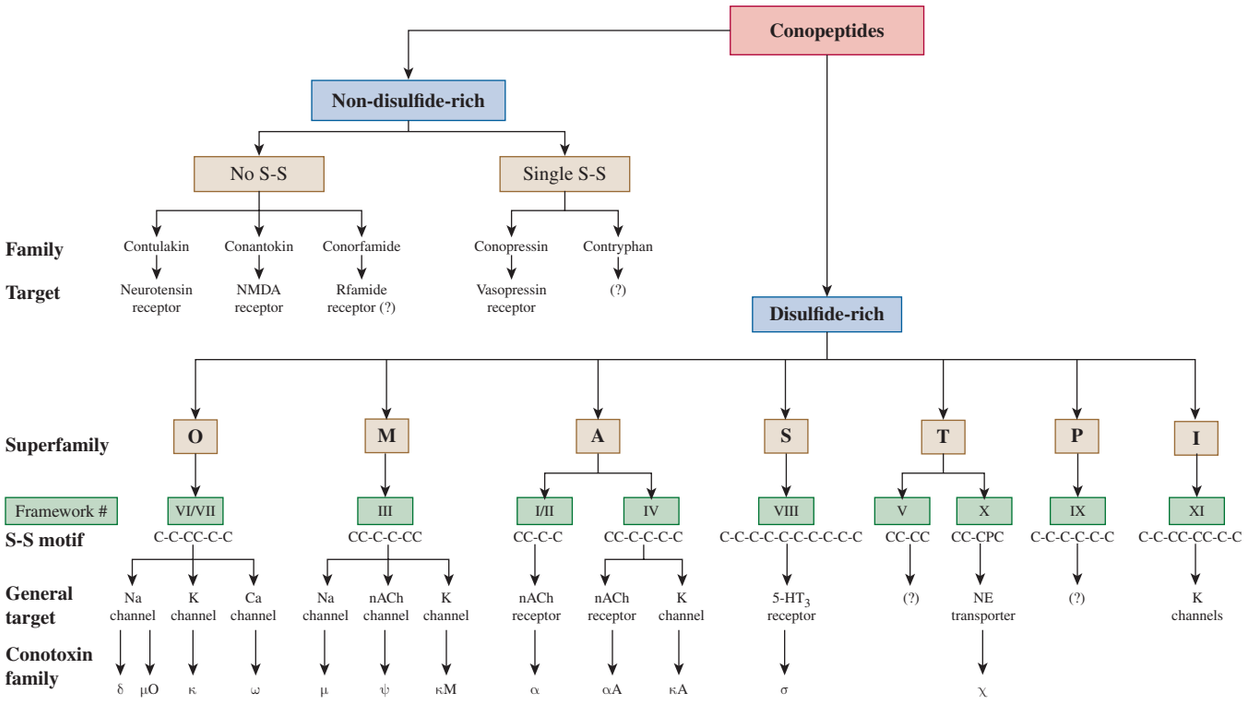

Figure 26-27. *Organizational diagram for Conus peptides, indicating gene superfamilies, disulfide patterns, and known pharmacologic targets.* Only the superfamilies of the disulfide-rich peptides are shown. (Used with permission from Terlau and Olivera [2004].)

Cone snails could be called sophisticated practitioners of combination drug therapy. After injection, multiple conopeptides act synergistically to affect the targeted prey. The term "toxin cabal" has been applied to this coordinated action of the conopeptide mixture. The fish-hunting species *Conus purpurascens* apparently has two distinct cabals whose effects differ in time and space. The "lightning-strike cabal" causes immediate immobilization of the injected prey because various venom components inhibit voltage-gated sodium channel inactivation and block potassium channels, resulting in massive depolarization of axons near the injection site and a tetanic state. The second physiologic cabal, the "motor cabal," acts more slowly as conotoxins must distribute throughout the body of the prey. The overall result is total inhibition of neuromuscular transmission. Various conopeptides inhibit presynaptic calcium channels that control neurotransmitter release, the postsynaptic neuromuscular nicotinic receptors, and the sodium channels involved in the muscle action potential (Terlau et al., 1996).

Conopeptides can affect many ion channels (Olivera et al., 1994; Terlau and Olivera, 2004). For example, μ-conotoxins are peptides with 22 to 25 amino acids and six cysteine residues that block sodium currents by acting at a site that overlaps the tetrodotoxin-sensitive site of sodium channels. The main effect of the unusually hydrophobic δ-conotoxins, which are peptides with an inhibitory cysteine knot motif pattern of disulfide bridges, is the inhibition of the fast inactivation of sodium currents, which affects the shape and duration of the action potential. This can lead to a massive electrical hyperexcitation of the complete organism. The κ-, κA-, and κM-conotoxins target potassium channels. The ω-conotoxins are peptides that target calcium channels, and these toxins have been widely used in neuroscience research. A characteristic feature of the ω-conotoxins is their high content of basic amino acids. One peptide, ω-conotoxin MVIIA from *Conus magus*, has been developed as ziconotide (Prialt®) for the treatment of intractable pain (Olivera, 2000). Other conotoxins are being studied as potential antinociceptive agents.

Conopeptides also target ligand-gated ion channels that mediate fast synaptic transmission (Kandel et al., 2013). One major group of ligand-gated ion channels is activated by acetylcholine, serotonin, γ-aminobutyric acid, or glycine. These proteins differ in ligand specificity and selectivity for the permeant ion. The second family activates the glutamate receptors, *N*-methyl-D-aspartate and kainate/AMPA receptors. A third group activates synaptic transmission at certain synapses via the ATP receptors. It is evident from Fig. 26-27 that there are conopeptides that target these three different families of ligand-gated ion channels. It is clear that our understanding of the structure and function of conopeptides is rapidly expanding and additional information regarding these toxins is available in some excellent reviews (Terlau and Olivera, 2004; Lewis et al., 2012; Kumar et al., 2015; Lebbe and Tytgat, 2016; Mir et al., 2016).

REPTILES

Lizards

The Gila monster (*Heloderma suspectum*; Fig. 26-28) and the beaded lizards (*Heloderma horridum*) are divided into five subspecies. These large, corpulent, relatively slow moving, and largely nocturnal reptiles have few enemies other than humans. They are far less dangerous than is generally believed. Their venom is transferred from venom glands in the lower jaw through ducts that discharge their contents near the base of the larger teeth of the lower jaw. The venom is then drawn up along grooves in the teeth by capillary action (Brown and Carmony, 1991). The venom of this

Figure 26-28. *Heloderma suspectum (Gila monster).*

lizard has serotonin, amine oxidase, phospholipase A, a bradykinin-releasing substance, helodermin, gilatoxin, and low-proteolytic as well as high-hyaluronidase activities, but lacks phosphomonoesterase and phosphodiesterase, acetylcholinesterase, nucleotidase, ATPase, deoxyribonuclease, ribonuclease, amino acid oxidase, and fibrinogenocoagulase activities. The clinical presentation of a helodermatid bite can include algogenia, edema, hypotension, nausea, vomiting, weakness, and diaphoresis. No antivenin is commercially available. Treatment is supportive (Strimple et al., 1997).

The venom has been shown to contain a 25-kDa protein, helothermine, containing 223 amino acids and four pairs of disulfide bonds, which appears to inhibit Ca^{2+} flux from the sarcoplasmic reticulum (Morrissette et al., 1995; Nobile et al., 1996). A fraction causing hemorrhage in internal organs and the eye, a glycoprotein of 210 amino acid residues with plasma kallikrein-like properties, has also been described (Datta and Tu, 1997). A 35 amino acid residue, helodermin produces hypotension that is partially attributed to activation of glibenclamide-sensitive K^+ channels (Horikawa et al., 1998). In fact, helospectin I and II and helodermin are nonamidated peptides similar to vasoactive intestinal peptide that are isolated from the salivary gland venom of the lizards *H. suspectum* and *H. horridum*, which have strong and potent vasodilator effects (Uddman et al., 1999).

Snakes

General Information and Classification Snakes have a three-chambered heart and rely almost exclusively on an enlarged right lung (which spans approximately half of the body length) for respiration. Of the approximately 2700 known species of snakes, about 20% are considered to be venomous (Mebs, 2002; Mackessy, 2010). Venomous snakes primarily belong to the following families: Viperidae (vipers), Elapidae, Atractaspididae, and Colubridae. The vipers are further divided into subfamilies, an example of which is the Crotalinae, or pit vipers, which possess a pit between the eyes and nostrils that serves as a heat sensor to detect warm-blooded animals. Some of the subfamilies are regarded as separate families altogether depending on the classification scheme. Overall, the Colubridae are considered the largest venomous family, and are composed of nearly 60% of all snakes. The Atractaspididae family is known for burrowing into the ground and possessing the ability to expose their fangs without opening their mouth.

Another characteristic that is often used for self-defense or hunting prey is mimicry (O'Shea, 2011). Scale pattern and coloration provide distinct boundaries in the wild and often carry unspoken warnings based on a reputation for snake venom toxicity for a given species. If a relatively harmless species is able to mimic the physical characteristics, especially color patterns, of a well-known highly toxic counterpart, then other potential predators may recognize both snakes as toxic and not pursue either.

Fang anatomy and dentition are good indicators of such factors as snake habitat and feeding habits (O'Shea, 2011). In general, the anatomical structure of fangs makes it nearly impossible for snakes to chew their prey. The distinct curvature of the fangs is engineered not only for puncturing skin and delivering venom, but also for swallowing whole prey as well. The teeth and jaw structure are relatively mobile and effectively facilitate the positioning of whole prey for swallowing. The skull and jaw possess an extremely high degree of responsiveness to stimuli. The jaw does not actually dislocate; however, it is able to rapidly reposition itself to capture, contain, and swallow prey. In addition to the capabilities of the teeth, fangs, and jaws, the classic fork-shaped tongue is another tool for identifying prey (O'Shea, 2011).

The Viperidae fang structure is regarded as the most developed and efficient means of venom, or toxin, delivery to prey. The venom gland is positioned at the base of a long (about 30 mm) hollow retractable fang (Mebs, 2002; Weinstein et al., 2010). Muscle pressure on the gland determines the amount of venom released. Another highly developed venom delivery apparatus is characteristic of the spitting cobras, aptly named for their ability to project venom via glands that protrude from the base of the fang opening (Mebs, 2002). Venom is carried toward the prey, or target, via forceful exhalation that is accompanied by a hissing sound. Toxin delivery via venom exposure is the primary mechanism by which snakes immobilize and kill their prey. Toxin composition and toxicity differ depending on the species as most venoms consist of complex mixtures of components that affect variable organ systems and interact with one another increasing the overall potency.

It is estimated that there are over 2.5 million snakebites annually, and that over 100,000 victims will die (White, 2005; Mackessy, 2010). Information resources available to physicians on management of snakebite victims may be found at the Clinical Toxinology Resources Web site—www.toxinology.com—or other appropriate references (Dart, 2004; Tintinalli et al., 2016; Corbett and Clark, 2017).

Snake Venoms These venoms are complex mixtures: proteins and peptides, consisting of both enzymatic and nonenzymatic compounds, make up over 90% of the dry weight of the venom (Phui Yee et al., 2004). Snake venoms also contain inorganic cations such as sodium, calcium, potassium, magnesium, and small amounts of zinc, iron, cobalt, manganese, and nickel. The metals in snake venoms are likely catalysts for metal-based enzymatic reactions. For example, in the case of some elapid venoms, zinc ions appear to be necessary for anticholinesterase activity, and calcium may play a role in the activation of phospholipase A and the direct lytic factor. Some proteases appear to be metalloproteins. Some snake venoms also contain carbohydrates (glycoproteins), lipids, and biogenic amines, such as histamine, serotonin, and neurotransmitters (catecholamines and acetylcholine) in addition to positively charged metal ions (Russell, 2001; Mebs, 2002; Ménez, 2003; Ramos and Selistre-de-Araujo, 2006; McCleary and Kini, 2013; Nery et al., 2016; Boldrini-França et al., 2017; Silva et al., 2017). The complexity of snake venom components is illustrated nicely in Fig. 26-29 (Ramos and Selistre-de-Araujo, 2006).

Actions of snake venoms can be said to be broad ranging in several areas (O'Shea, 2011). A simplistic approach would group toxin components as neurotoxins, coagulants, hemorrhagins,

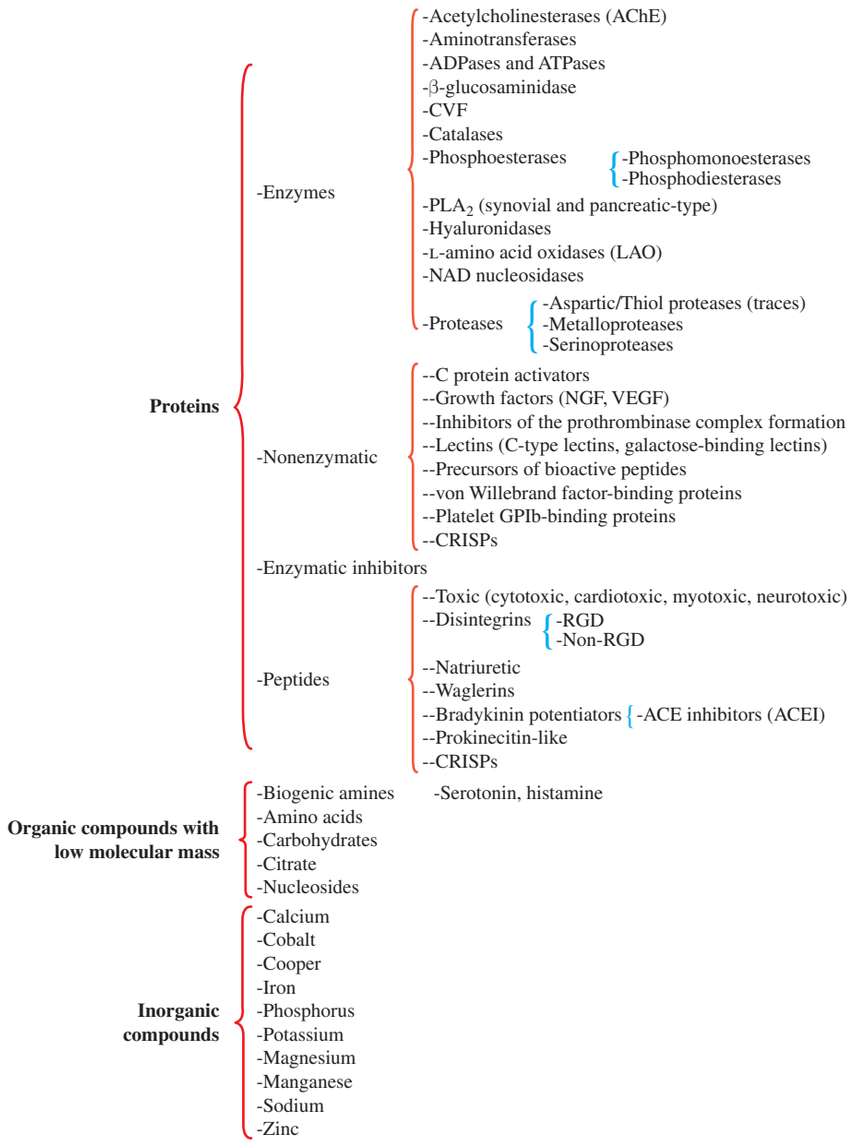

Figure 26-29. *Components of snake venoms.* ACE, angiotensin-converting enzyme; CRISP, cysteine-rich secretory protein; CVF, cobra venom factor–like proteins; LAO, L-amino acid oxidase; PLA_2, phospholipase A2; RGD, arginine–glycine–aspartate. (Used with permission from Ramos and Selistre-de-Araujo [2006].)

hemolytics, myotoxins, cytotoxins, and nephrotoxins. Neurotoxins produce neuromuscular paralysis ranging from dizziness to ptosis; to ophthalmoplegia, flaccid facial muscle paralysis, and inability to swallow; to paralysis of larger muscle groups; and finally to paralysis of respiratory muscles and death by asphyxiation. Coagulants may have initial procoagulant action that uses up clotting factors leading to bleeding. Coagulants may directly inhibit normal clotting at several places in the clotting cascade or via inhibition of platelet aggregation. In addition, some venom components may damage the endothelial lining of blood vessels leading to hemorrhage. Bite victims may show bleeding from nose or gums, from the bite site, and in saliva, urine, and stools. Myotoxins can directly affect muscle contraction leading to paralysis or cause rhabdomyolysis or the breakdown of skeletal muscle. Myoglobinuria, or a dark brown urine, and hyperkalemia may be noted. Cytotoxic agents have proteolytic or necrotic properties leading to the breakdown of tissue. Typical signs include massive swelling, pain, discoloration, blistering, bruising, and wound weeping. Sarafotoxins, which are found only in burrowing asps of Afro-Arabia, cause coronary artery constriction that can lead to reduced coronary blood flow, angina, and myocardial infarction. Finally, nephrotoxins can cause direct damage to kidney structures leading to bleeding, damage to several parts of the nephron, tissue oxygen deprivation, and renal failure.

Enzymes At least 26 different enzymes have been isolated from snake venoms, which can be a sequence of 150 to 1500 amino acids (Ménez, 2003). No single snake venom contains all 26 enzymes and some important snake venom enzymes are shown in Fig. 26-29.

Proteolytic enzymes that catalyze the breakdown of tissue proteins and peptides include peptide hydrolases, proteases, endopeptidases, peptidases, and proteinases. Several proteolytic enzymes may be in a single venom. The proteolytic enzymes have molecular

Figure 26-30. *Crotalus atrox (western diamondback rattlesnake).*

Figure 26-31. *Oxyuranus scutellatus (Australian costal taipan).*

weights between 20,000 and 95,000. Some are inactivated by ethylenediaminetetraacetic acid (EDTA) and certain reducing agents. Metals appear to be intrinsically involved in the activity of certain venom proteases and phospholipases. The crotalid venoms examined so far appear to be rich in proteolytic enzyme activity. Viperid venoms have lesser amounts, whereas elapid and sea snake venoms have minimal, if any, proteolytic activity. Venoms that are rich in proteinase activity are associated with marked tissue destruction (Russell, 2001; Serrano, 2013).

Collagenase is a specific kind of proteinase that digests collagen. This activity has been demonstrated in the venoms of a number of species of crotalids and viperids. The venom of *Crotalus atrox* (Fig. 26-30) digests mesenteric collagen fibers but no other proteins. EDTA inhibits the collagenolytic effect, but not the arginine esterase effect.

Hyaluronidase cleaves internal glycoside bonds in certain acid mucopolysaccharides resulting in a decrease in the viscosity of connective tissues. The breakdown in the hyaluronic barrier allows other fractions of venom to penetrate the tissues, causing hyaluronidase to be called "spreading factor." The degree to which hyaluronidase contributes to the extent of edema produced by the whole venom is not known (Kemparaju et al., 2010).

Phospholipase A_2 (PLA_2) enzymes are widely distributed throughout the tissues of animals, plants, and bacteria, and have been well studied in snake venoms (Ohno et al., 2003; Soares and Giglio, 2003; Doley et al., 2010). Mammalian PLA_2 enzymes are involved in fertilization and cell proliferation, and have been implicated in respiratory ailments such as asthma, as well as skin conditions such as psoriasis (Kini, 2003; Soares and Giglio, 2003). PLA_2 catalyzes the Ca^{2+}-dependent hydrolysis of the 2-acyl ester bond, producing free fatty acids and lysophospholipids. However, liberation of pharmacologically active products and effects independent of enzymatic action may contribute to their overall action. In general, mammalian PLA_2s are considered to be nontoxic and do not elicit the same pharmacologic effects as similar enzymes in snake venoms.

As of 2003, over 280 PLA_2 enzymes had been classified, sharing at least 40% identity in their amino acid sequences (Kini, 2003; Soares and Giglio, 2003). Many PLA_2s have been sequenced. They have approximately 120 amino acids and 14 cysteine residues forming seven disulfide bonds. Surface residue recognition and covalent/noncovalent bonds stabilize complexes for receptor binding. Specific amino acid residues play an important role in the diversification and overall function of the PLA_2s. Of note, histidine, lysine, cysteine, and methionine have been well studied for their contribution to enzyme structure and function (Soares and Giglio, 2003). For example, alkylation of His48 diminishes the hydrolytic capabilities of certain toxins. Alkylation of amino acids has proven to effectively mitigate PLA_2 toxicity and has been proposed as an antivenom treatment (Soares and Giglio, 2003). PLA_2s interact with other toxins in the venom as well, often resulting in synergistic reactions. Similarly, snake venom PLA_2 enzymes can be separated into three major groupings depending on their pharmacologic activities: low-toxicity enzymes ($LD_{50} > 1$ mg/kg), high-toxicity enzymes ($1 \text{ mg/kg} > LD_{50} > 0.1$ mg/kg), and presynaptically acting toxins ($LD_{50} < 0.1$ mg/kg) (Rosenberg, 1990). Although the sequences of these enzymes are homologous and their enzymatically active sites are identical, they differ widely in their pharmacologic properties. For example, taipoxin, a PLA_2 enzyme from the venom of the Australian elapid *Oxyuranus scutellatus* (Fig. 26-31), has an intravenous LD_{50} in mice of 2 μg/kg, whereas the neutral PLA_2 from *Naja nigricollis* (Fig. 26-32) has an LD_{50} of 10,200 μg/kg, even though *N. nigricollis* PLA_2 is enzymatically more active (Russell, 2001).

Arginine ester hydrolase is one of a number of noncholinesterases found in snake venoms. The substrate specificities are directed to the hydrolysis of the ester or peptide linkage, to which an arginine residue contributes the carboxyl group. This activity

is found in many crotalid and viperid venoms and some sea snake venoms, but is lacking in elapid venoms with the possible exception of *Ophiophagus hannah*. Some crotalid venoms contain at least three chromatographically separable arginine ester hydrolases. The bradykinin-releasing and perhaps bradykinin-clotting activities of some crotalid venoms may be related to esterase activity.

Two distinct classes of fibrin(ogen)olytic enzymes, the metalloproteinases and the serine proteinases, have been isolated from venom of Viperidae, Elapidae, and Crotalidae snake families (Swenson and Markland, 2005). These two classes of proteinases differ in mechanism of action and their target in fibrin(ogen), but ultimately they break down fibrin-rich clots and help to prevent further clot formation. The properties of fibrolase, an α-chain fibrinolytic metalloproteinase from *Agkistrodon contortrix contortrix* (Fig. 26-33) venom, and β-fibrinogenase, a β-chain fibrinogenase from *Vipera lebetina*, are provided in Table 26-13. Properties of some additionally characterized fibrin(ogen)ases are listed in Table 26-14. It is apparent that there are major differences in the properties of these enzymes from different snakes even though they have similar catalytic properties. An exciting development from the research on these enzymes is that one specific recombinant fibrinolytic enzyme derived from fibrolase called alfimeprase is progressing through clinical trials for the treatment of peripheral arterial occlusions.

The snake venom metalloproteinases (SVMPs) are enzymes that disrupt the hemostatic system and they are characterized by their domain structure into four primary classes, PI to PIV (Fox and Serrano, 2010; Markland and Swenson, 2013). SVMPs are synthesized in vivo as multimodular proteins that comprise a signal peptide, a prodomain, and a metalloprotease domain (SVMP PI). SVMP potency tends to increase by class and those within the PIV class are larger and comprise additional disulfide bonds (Calvette et al., 2003, 2005). Class PII proteins exhibit a C-terminal disintegrin domain. The PII metalloproteases block the function of integrin receptors, a function that could alleviate a variety of pathological conditions such as inflammation, tumor angiogenesis and metastasis, and thrombosis. The integrin-blocking specificity of this class of metalloproteins is highly dependent on the conformation of the inhibitory loop, and thus the placement and bonding of cysteine residues. More specifically, within the inhibitory loops, RGD-containing disintegrins are specific to the class PII metalloproteases

Table 26-14

Biological and Physiological Properties of Specific Fibrin(ogen)ases

(Calvette et al., 2003, 2005). Class PIII SVMPs exhibit the disintegrin-like domain and the C-type lectin-like domain is present in PIV SVMPs. The metalloproteinase domain or catalytic domain is composed of about 215 amino acids and has metal-dependent endopeptidase activity (Calvette et al., 2005). SVMPs degrade proteins such as laminin, fibronectin, type IV collagen, and proteoglycans from the endothelial basal membrane; degrade fibrinogen and von Willebrand factor enhancing the hemorrhagic action; and inhibit platelet aggregation and stimulate release of cytokines (Ramos and Selistre-de-Araujo, 2006).

The proteolytic action of thrombin and thrombin-like snake venom enzymes is shown in Table 26-15. This table compares ancrod (from *Calloselasma rhodostoma*), batroxobin (from *Bothrops moojeni*), crotalase (from *Crotalus adamanteus*), gabonase (from *Bitis gabonica*), and the enzyme from *A. contortrix*. Table 26-16 shows the molecular size of some thrombin-like enzymes. A recent contribution on snake toxins, using mass spectrometric immunoassay and bioactive probe techniques, has been published by Ramirez et al. (1999a, 1999b). Considerable study has been given to the hemostatic properties of venoms (Markland, 1998; Phillips et al., 2010). The hemostatically active components are summarized in Table 26-17.

Phosphomonoesterase (phosphatase) is widely distributed in the venoms of all families of snakes except the colubrids (Dhananjaya et al., 2010). It has the properties of an orthophosphoric monoester phosphohydrolase. There are two nonspecific phosphomonoesterases, and they have optimal pH at 5.0 and 8.5. Many types of venom contain both acid and alkaline phosphatases, whereas others contain one or the other.

Phosphodiesterase has been found in the venoms of all families of poisonous snakes. The enzyme is an orthophosphoric diester phosphohydrolase that releases 5-mononucleotide from the polynucleotide chain, and thus acts as an exonucleotidase, attacking DNA and RNA. More recently, it has been found that it also attacks derivatives of arabinose.

Table 26-16

Comparison of Snake Venom Thrombin-Like Enzymes

VENOM ENZYME	MOLECULAR WEIGHT	CARBOHYDRATE CONTENT (%)	ACTIVE SITE SERINE
Agkistrodon contortrix contortrix	100,000	ND	+

Snake Venom Proteins Active on the Hemostatic System

GENERAL FUNCTIONAL ACTIVITY	SPECIFIC BIOLOGICAL ACTIVITY
Procoagulant	Activates factors II, V, IX, X, and protein C Fibrinogen clotting
Anticoagulant	Factor IX/factor X–binding protein Thrombin inhibitor Phospholipase A
Fibrinolytic	Fibrin(ogen) degradation Plasminogen activation
Vessel wall interactive	Hemorrhagic

SOURCES: Data from Markland (1998) and Russell (2001).

Acetylcholinesterase was first demonstrated in cobra venom and is widely distributed throughout the elapid venoms (Ahmed et al., 2010). It is also found in sea snake venoms but is totally lacking in viperid and crotalid venoms. It catalyzes the hydrolysis of acetylcholine to choline and acetic acid. The role of the enzyme in snake venoms is not clear, but may function to catalyze the hydrolysis of acetylcholine, thereby facilitating tetanic paralysis and capture of prey.

RNase is present in some snake venoms in small amounts as the endopolynucleotidase RNase. It appears to have specificity toward pyrimidine-containing pyrimidyladenyl bonds in DNA. The optimum pH is 7 to 9 when ribosomal RNA is used as the substrate. This enzyme in *Naja oxiana* venom has a molecular weight of 15,900.

DNase acts on DNA to produce predominantly trinucleotides or higher oligonucleotides that terminate in 3′-monoesterified phosphate. *C. adamanteus* venom contains two DNases, with optimum pH at 5 and 9.

5′-Nucleotidase is a common constituent of all snake venoms; in most instances, it is the most active phosphatase in snake venoms. It specifically hydrolyzes phosphate monoesters, which link with a 5′ position of DNA and RNA. It is found in greater amounts in crotalid and viperid venoms than in elapid venoms. The molecular weight as determined from amino acid composition and gel filtration with *Naja naja atra* venom has been estimated at 10,000. The enzyme from *N. naja* venom is enhanced by Mg^{2+}, is inhibited by Zn^{2+}, is inactivated at 75°C at pH 7.0 or 8.4, and has an isoelectric point of about 8.6. The enzyme from *Agkistrodon halys blomhoffi* shows a pH optimum of 6.8 to 6.9, with activity being enhanced by Mg^{2+} and Mn^{2+} and inhibited by Zn^{2+}. The enzyme has a low order of lethality (Russell, 2001).

Nicotinamide adenine dinucleotide (NAD) nucleotidase has been found in a number of snake venoms. This enzyme catalyzes the hydrolysis of the nicotinamide *N*-ribosidic linkage of NAD, yielding nicotinamide and adenosine diphosphate riboside. Its optimum pH is 6.5 to 8.5; it is heat labile, losing activity at 60°C. Nucleotidases function as ADP scavengers, thereby acting as potent inhibitors of platelet aggregation.

L-Amino acid oxidase has been found in all snake venoms examined so far and it is what gives the characteristic yellow color to the venom. This enzyme catalyzes the oxidation of L-α-amino and α-hydroxy acids. This activity results from a group of homologous enzymes with molecular weights ranging from 85,000 to 150,000. The mouse intravenous LD_{50} of the enzyme from *C. adamanteus* venom was 9.13 mg/kg body weight, approximately four times less than the lethal value of the crude venom, and this enzyme had no effect on nerve, muscle, or neuromuscular transmission (Russell, 2001; Tan and Fung, 2010).

Polypeptides Snake venom polypeptides are low-molecular-weight proteins that do not have enzymatic activity. More than 80 polypeptides with pharmacologic activity have been isolated from snake venoms. Interested readers will find definitive reviews on these peptides in the works of Lee (1979), Eaker and Wadström (1980), and Gopalakrishnakone and Tan (1992). Most of the lethal activity of the poison of the sea snake *Laticauda semifasciata* was recovered as two toxins, erabutoxin-a and erabutoxin-b, using carboxymethylcellulose chromatography; 30% of the proteins were erabutoxins. More recently, erabutoxin-a, a short-chain curamimetic, has been crystallized in monomeric and dimeric forms (Nastopoulos et al., 1998). Erabutoxin-b is said to be relatively ineffective at the mammalian neuromuscular junction (Vincent et al., 1998). Another curamimetic, a long-chain polypeptide, is α-cobratoxin, while a novel "neurotoxin" from *N. naja atra*, having 61 amino acid residues and eight cystine residues, has been isolated by Chang et al. (1997).

Disintegrins are a family of short cysteine-rich polypeptides and are divided into five subgroups based on the combination of length and number of disulfide bonds of polypeptides. In general, the disintegrins comprise 40 to 100 amino acids. Their small size coupled with a relatively dense network of disulfide bonds contributes to the tertiary structure of these compounds and high potency of such small compounds. Disintegrins are released in venoms via proteolytic processes of PII metalloproteinases, whereas structures similar in form and function to disintegrins, or disintegrin-like, are subject to PIII processes (Calvette et al., 2005). Monomeric disintegrins can vary from about 50 residues and four disulfide bonds as in echistatin and obtustatin to around 70 amino acid residues and 6 disulfide bridges as in albolabrin, barbourin, and halysin, to over 84 amino acids and 7 disulfide bonds for bitistatin and salmosin-3. Dimeric disintegrins are about 67 amino acids long and contain 4 intrachain disulfide linkages and 2 between-chain bonds. Examples include contortrostatin and acostatin. The monomeric disintegrin-like chemicals contain around 100 amino acids and 8 disulfide bonds, and include trimelysin-I, bothropasin, and jararhagin (Calvette et al., 2003; Ramos and Selistre-de-Araujo, 2006).

RGD (argine–glycine–asparagine) and non-RGD-containing disintegrins coexist in certain venoms and exhibit affinities for variable ligand receptors. In such cases, one copy of the gene encodes for the more conserved RGD function of platelet aggregation, whereas the duplicated genes have drifted toward facilitating other biological functions. Modeling and structure analysis of cyclic RGD peptides has implicated the importance of amino acid sequences on the C-terminal of the RGD sequence; furthermore, the physical features such as size of the integrin-binding loop contribute to the receptor-binding capabilities (Calvette et al., 2005). In general, the amino acid residues of this region of the RGD sequence are not well conserved and are thought to play a key role in determining integrin receptor-binding specificity. There are additional mechanisms within the C-terminal region, which include conformational epitopes that are utilized to alter receptor-binding capabilities.

The small basic polypeptide myotoxins are widely distributed in *Crotalus* snake venoms. The specific agent crotamine from *Crotalus durissus terrificus* venom induces skeletal muscle spasms

and paralysis by changing the inactivation process of sodium channels, which are inhibited by tetrodotoxin and potentiated by veratridine and grayanotoxin, leading to depolarization of the neuromuscular junction. Crotamine is composed of 42 amino acid residues and 3 disulfide bonds. The crotamine gene contains 1.8 kbp and has three exons that are separated by a long phase-1 and a short phase-2 intron and mapped to chromosome 2. In addition, the three-dimensional structure has been published, and the structural topology is similar to that of other three disulfide bridge containing peptides such as human β-defensins and scorpion sodium channel toxin. These structural properties enable crotamine to have a unique cell-penetrating ability allowing the toxin to concentrate in the nucleus by means of a probable receptor-independent mechanism. It is interesting to note that topology and diversification of functional folds are common themes in animal venom peptides acting on ion channels and other targets (Ménez, 1998; Mouhat et al., 2004; Oguiura et al., 2006).

Toxicology In general, the venoms of rattlesnakes and other New World crotalids produce alterations in the resistances and often in the integrity of blood vessels, changes in blood cells and blood coagulation mechanisms, direct or indirect changes in cardiac and pulmonary dynamics, and—with crotalids such as *C. durrissus terrificus* and *C. scutulatus*—serious alterations in the nervous system and changes in respiration. In humans, the course of the poisoning is determined by the kind and amount of venom injected; the site where it is deposited; the general health, size, and age of the patient; the kind of treatment; and those pharmacodynamic principles noted earlier in this chapter. Death in humans may occur within less than 1 hour or after several days, with most deaths occurring between 18 and 32 hours. Hypotension or shock is the major therapeutic problem in North American crotalid bites (Russell, 2001).

Snakebite Treatment The treatment of bites by venomous snakes is now so highly specialized that almost every envenomation requires specific recommendations. However, three general principles for every bite should be kept in mind: (1) snake venom poisoning is a medical emergency requiring immediate attention and the exercise of considerable judgment; (2) the venom is a complex mixture of substances of which the proteins contribute the major deleterious properties, and the only adequate antidote is the use of specific or polyspecific antivenom; and (3) not every bite by a venomous snake ends in an envenomation. Venom may not be injected. In almost 1000 cases of crotalid bites, 24% did not end in a poisoning. The incidence with the bites of cobras and perhaps other elapids is probably higher. The reader is referred to other appropriate texts for appropriate treatment of snakebites (Dart, 2004; Singletary and Holstege, 2006; Smith and Bush, 2010; Tintinalli et al., 2016; Auerbach et al., 2017; see also Clinical Toxinology Resources, www.toxinology.com.).

Snake Venom Evolution Considerable efforts are being expended to examine the complex process by which snake venom components are thought to have changed over the years. This evaluation involves tracing the ancestral roots of toxins, which is made even more cumbersome due to the distinct differences in the speed at which individual components of a venom evolve. The current assemblage of snake venoms with regard to functionality and ancestral protein activity is outlined in Table 26-18 (Fry, 2005). In general, the toxins from ancestral proteins that were constructed of dense networks of cysteine cross-linkages are considered among the most diverse today in terms of toxicological insult.

The evolution of the PLA_2s appears to be directed toward modifying the molecular surface in order to maximize the diversity of the pharmacologic properties of each isozyme component (Kini and Chan, 1999; Li et al., 2005). As PLA_2s are not crucial for snake survival, mutations in some PLA_2 isozymes may be ignored and allowed to progress, thereby expediting the evolution in comparison to other more critical enzymes in which mutations are monitored more closely and not allowed to progress. The functionality of PLA_2 isozymes can be significantly hindered by increased rates of mutations within highly conserved regions of the amino acid sequence, which could in turn displace cysteine residues and alter the tertiary protein structure. However, increased mutation of a particular subset of enzymes, such as the PLA_2s, may be a result of a shift in ecological niche. A recent study (Li et al., 2005) reports a shift in the diet composition of the marbled sea snake as the root cause of decelerated evolution of the PLA_2 enzymes. The diet change from live prey to fish eggs essentially negated the need for PLA_2 enzymes to immobilize live prey for swallowing and digestion. Future research could focus on the declining need for PLA_2s, and on the altered digestive enzyme composition that has likely occurred as a result of diet shift.

Table 26-18

Basal Bioactivities of Some Toxin Types

TOXIN	ACTIVITY
3FTx	α-Neurotoxicity, blocks nicotinic acetylcholine receptor
ADAM	In Viperidae venoms, proteolytic cleavage of C-terminal domains results in direct fibrinolytic activity, liberation of disintegrins, which inhibit platelet aggregation
Cobra venom factor	Causes unregulated activation of complement cascade, hemolysis, and cytolysis
Crotamine	Myonecrosis, modifies voltage-gated sodium channels
Factor V	In taipan and brown snake venom, combines with toxic form of factor X to convert prothrombin to thrombin
Kallikrein	Increases vascular permeability, stimulates inflammation, and reduces blood pressure
Kunitz	Inhibits plasmin and thrombin and other serine proteases, blocks L-type calcium channels
L-Amino oxidase	Induces apoptosis, decreases platelet aggregation, inhibits blood factor IX
PLA_2	Releases arachidonic acid from phospholipids, resulting in inflammation and tissue destruction
VEGF	Increases permeability of vascular bed causing hypotension and shock
Whey acidic proteins	Inhibit leukoproteinases

SOURCE: Data from Fry (2005).

ANTIVENOMS

Antivenoms have been produced against most medically important snake, spider, scorpion, and marine toxins. Animals immunized with venom develop a variety of antibodies to the many antigens

in the venom. Antivenom consists of venom-specific antisera or antibodies concentrated from immune serum to the venom. Antisera contain neutralizing antibodies: one antigen (monospecific) or several antigens (polyspecific). Monovalent antivenoms have a high neutralization capacity, which is desirable against the venom of a specific animal. Polyvalent antisera are typically used to cover several venoms, such as snakes from a geographic region. Polyvalent preparations usually require higher doses or volumes than monovalent antivenoms. Neutralization capacity of antivenom is highly variable as there are no enforced international standards. Antivenom may cross-react with venoms from distantly related species and may not react with venom from the intended species. Nevertheless, in general, the antibodies bind to the venom molecules, rendering them ineffective.

Antivenoms are available in several forms: intact IgG antibodies or fragments of IgG such as $F(ab)_2$ and Fab. The molecular weight of the intact IgG is about 150,000, whereas that of Fab is approximately 50,000. The molecular size of IgG prevents its renal excretion and produces a volume of distribution much smaller than that of Fab. The elimination half-life of IgG in the blood is approximately 50 hours. Its ultimate fate is not known, but most IgG is probably taken up by the reticuloendothelial system and degraded with the antigen attached. Fab fragments have an elimination half-life of about 17 hours, and are small enough to permit renal excretion.

All antivenom products may produce hypersensitivity reactions. Type I (immediate) hypersensitivity reactions are caused by antigen cross-linking of endogenous IgE bound to mast cells and basophils. Binding of antigen by a mast cell may cause the release of histamine and other mediators, producing an anaphylactic reaction. Once initiated, anaphylaxis may continue despite discontinuation of antivenom administration. Type III hypersensitivity (serum sickness) may develop several days after antivenom administration. In these cases, antigen–antibody complexes are deposited in different areas of the body, often producing inflammatory responses in the skin, joints, kidneys, and other tissues. Fortunately, these reactions are rarely serious. The risks of anaphylaxis should always be considered when one is deciding whether to administer antivenom, and thus antivenom should be given only by intravenous infusion under medical supervision (Heard et al., 1999; Russell, 2001; Mebs, 2002; Dart, 2004; Tintinalli et al., 2016; Clinical Toxinology Resources, n.d.).

POTENTIAL CLINICAL APPLICATION OF VENOMS

Animal venoms are being used as research and clinical tools based on their high affinity for specific targets and well-studied pharmacologic properties (Ménez, 1998, 2003; Dimarcq and Hunneyball, 2003; Escoubas and Rash, 2004; Cherniack, 2010, 2011; Mayer et al., 2010; McCleary and Kini, 2013). Toxin specificities for receptors and channels that facilitate the interface and coordination of neuromuscular activity are utilized and manipulated to study, model, diagnose, and sometimes treat acute and degenerative conditions. On closer examination of α-bungarotoxin and candoxin nicotinic acetylcholine receptor specificity, plans are under way to utilize the reversible and irreversible receptor binding in muscular and neuronal tissues, respectively, in Alzheimer patients (Phui Yee et al., 2004). In addition to treating neurological diseases, specific α-toxins (longer chained) are also studied for their antiangiogenic capabilities in treating malignant tumor growth in patients suffering from small cell lung carcinoma (Tsetlin and Hucho, 2004). In cases such as this, there is an inherent trade-off between promoting some degree of neurological deficit in light of combating tumor growth. Toxins such as the snake venom thrombin–like enzymes are valuable tools in both research and therapeutic applications. Similarly, fibrin(ogen)olytic enzymes that break down fibrin-rich clots preventing further clot formation may be useful as controls in blood clotting research or to treat heart attacks and strokes (Castro et al., 2004; Marsh and Williams, 2005; Swenson and Markland, 2005). To facilitate research, the complement-activating cobra venom factor has been produced by recombinant techniques (Vogel et al., 2004). These pharmazooticals include reptilase-R, bothrocethin, stypven, ecarin, and protac.

Active research efforts have noted that animal venoms contain components that can reduce pain, can selectively kill specific cancers, may reduce the incidence of stroke via effects on blood coagulability, and function as antibiotics. Numerous compounds have been isolated from marine animals (Newman et al., 2009; Bingham et al., 2010), including the anticancer agents plinabulin, tasidotin, bryostatin 1, hemiasterlin, and salinosporamide A (also known as marizomib). The compound epibatidin comes from the skin of the South American frog, *Epipedobates tricolor*, and a synthetic derivative ABT-594 appears to be more effective than morphine without being addictive. TM 601 is derived from the Israeli yellow scorpion and attacks malignant brain tumors called glioma tumors responsible for two-thirds of the cases of brain cancer, without harming healthy cells. ET 743, which comes from sea squirts, is being tested for treatment of ovarian cancer and soft tissue sarcoma. Ancrod is an anticoagulant with potential to prevent cell damage and death when someone suffers a stroke. The active ingredient comes from the venom of the Malaysian pit viper. In Germany, where Ancrod has been marketed for a number of years, a specially built facility houses about 3000 snakes. Several other sources of anticoagulants are being examined. A substance called magainin 2, which comes from the skin of frogs, is an effective antibiotic to which bacteria do not appear to develop resistance. The clotting enzyme batroxobin is an ingredient in reptilase and has been used in the development of fibrin glue, which is used in surgery to stop diffuse bleeding from liver or lung by covering the surface with a thin layer of fibrin.

Another major area of investigation and success involves the venom components that act as enzyme inhibitors. In particular, venom peptides from *Bothrops jararaca* were initially called bradykinin-potentiating peptides and lowered blood pressure. After further research, it became clear that these peptides were inhibitors of angiotensin I–converting enzyme, and chemical modification leads to orally active agents such as captopril.

Venom toxins can also be used as a component of the toxin–receptor–antibody complex for diagnosis of autoimmune disorders (Ménez, 2003). In addition to providing a promising means for researching and treating muscular and neurological diseases and cancer, work is being conducted on designing methods by which to consistently reconstruct and conform the overall toxin structure to bind to a specific protein, such as HIV (Ménez, 2003).

The venoms of the spider *Phoneutria nigriventer* and the yellow South American scorpion *Tityus serrulatus* are known to cause priapism. While erectile dysfunction is a growing health problem, the use of animal venoms and toxins as pharmacological tools could not only illuminate the mechanisms involved in erectile function, but also potentially create a possible model for new drugs to treat erectile dysfunction (Nunes et al., 2013).

It has been shown that leeches, earthworms, helminths, snails, centipedes, spiders, and ticks all produce substances with potential clinical applications, such as osteoarthritis, deep vein thrombosis, antimicrobial action, inflammatory bowel disease, analgesia, and hyperlipidemia (Cherniack, 2011). In particular, approximately 14

anticoagulant chemicals have been isolated from the leech, including hirudin and lepirudin, apyrase, collagenase, hyaluronidase, and eglin (Lubenow and Greinacher, 2002; Massart et al., 2009). Tick saliva contains proteins that inhibit human kallikrein and factors XIa and XIIa (Mazzuca et al., 2007). Earthworms contain proteins with anticoagulant, antimicrobial, and anti-inflammatory bowel disease properties (Joo et al., 2009; Reddy and Fried, 2009; Ruyssers et al., 2010). Bees can provide honey, royal jelly, and propolis, which all have antimicrobial properties, and the venom contains apamin and mellitin, which have anti-inflammatory properties. Additional details of the clinical applications of animal saliva and venom may be found in Cherniack (2010, 2011).

There have been numerous success stories: captopril, an angiotensin converting enzyme inhibitor for hypertension was patterned after a Brazilian viper venom peptide (Koh and Kini, 2012); ziconotide, a conotoxin from Conus magus, is used to treat pain (Webster and Fakata, 2005); and exenatide from Gila monster venom is used in type 2 diabetes treatment (Furman, 2012). Much exciting work will no doubt lead to other new therapeutic compounds as the exploration and harvest of natural products continues (Harvey, 2014; Verdes et al., 2016)

Additional work is being conducted on animals such as the mongoose, hedgehog, and opossum, which all embody a high level of resistance to snakebites. Blood from these animals contains proteins between 400 and 700 amino acids long that inhibit hemorrhagins. The exact mechanism of the many components in animal venoms that produce toxicity or resistance to certain toxins has yet to be determined. Further research will require a multidisciplinary approach involving techniques from parasitology, chemistry, molecular biology, genomics, proteomics, physiology, pharmacology, and toxicology.

CONCLUSION

The myriad toxins produced by plants and animals range from the relative simplicity of small chemicals to the exceedingly complex proteinaceous toxins. The effects of these compounds are amazingly diverse and can range from local irritation to systemic destruction and death. The interplay between toxin and organism is often difficult to study due to difficulty involved in recreating the interaction in the laboratory. One must also not forget the interactions that arise between toxins and substances already present in the organism. These interactions can act to worsen or reduce the poisonous outcome. As laboratory techniques become more sophisticated and new methods are developed, research concerning toxins and their effects will continue to grow.

ACKNOWLEDGMENTS

The editor and author recognize the contributions of previous authors of this chapter: chapters on plant: John M. Kingsburg (1st and 2nd editions), Kenneth F. Lampe (3rd and 4th editions), and Stata Norton (5th to 7th editions); chapters on animal: Frederick W. Oehme, John F. Brown, and Murray E. Fowler (1st and 2nd editions), Findlay E. Russell (3rd to 6th editions), and Findlay E. Russell and Richard C. Dart (4th edition).

INTRODUCTION TO FOOD TOXICOLOGY

Food is one of the most essential materials for the survival of living organisms, in addition to oxygen and water. Food toxicology deals with the substances found in food that, when consumed, may cause harm to the consumers. Therefore, the practice of food toxicology involves detecting toxic substances in food, characterizing their properties, studying their fate in the body (absorption, distribution, metabolism, and excretion), and investigating their adverse health effects. Toxic substances can be naturally present in food, formed when the food is cooked, added directly to food, or they can find their way into food from the immediate environment, such as packaging. Among various subdisciplines of toxicology, food toxicology has received wider public attention in recent years. This has been driven by an increased awareness of the health effects of foods, foodborne illness, as well as the rapid availability of information to consumers, thanks to the world-wide-web.

Typically, a food contains hundreds of substances. Apart from the most obvious constituents, a majority of the substances in various foods have not been fully characterized. The assumption that food is safe to consume is based on the history of its consumption. In recent years, there has been increasing interest on the part of consumers regarding the "health-promoting" properties of various naturally occurring constituents of food, such as phytosterols from vegetable oils and isoflavones from soy. The addition of substances to foods that do not contain them naturally has raised questions about how they should be regulated. There is a debate whether the concept of nutrients should be expanded to include a growing number of food constituents that seemingly produce health benefits (Sansalone, 1999). Because federal dietary guidance applies to the total diet and there are no widely accepted standards to judge the "healthfulness" of individual foods, fortification of foods with new substances should require a thorough evaluation of safety at the intended level of intake for the general population (Mackey and Kotsonis, 2002).

NATURE AND COMPLEXITIES OF FOOD

Food is a very complex mixture of nutrient and non-nutrient substances, whether it is consumed uncooked (e.g., raw agricultural product) or in a cooked and highly processed ready-to-eat form (Tables 27-1 and 27-2). Many of the non-nutrient substances are necessary for the growth and survival of the plant (from which they are derived), and for the plant's adaptation to the environment. Some of these substances may act as antinutrients rather than frank toxins, such as trypsin and chymotrypsin inhibitors, phytates that bind minerals, anti-thiamines in fish and plants, etc. Traditionally, the nutrients in food are classified as calorigenic *macronutrients*, such as carbohydrates, proteins, and fats, and the non-calorigenic *micronutrients*, such as vitamins and minerals.

The Food and Nutrition Board of the Institute of Medicine (IOM), which is a division of the U.S. National Academies of Sciences, Engineering and Medicine (NAS), has developed Dietary Reference Intakes (DRIs) that serve as a guide for good nutrition. Since 1994 the IOM's Food and Nutrition Board has been involved in developing an expanded approach to establish dietary reference standards. This approach, the DRIs, provides a set of four nutrient-based reference values designed to replace the

Table 27-1
Food as a Complex Mixture

NUTRIENTS		NON-NUTRIENTS
Macronutrients	Micronutrients	Naturally occurring substances
Carbohydrates	Vitamins	Food additives (direct, indirect)
Total fiber	Minerals	Contaminants
Proteins		Products of food processing
Fats		

Table 27-2
Non-nutrient Substances in Some Common Food

FOOD	NUMBER OF IDENTIFIED NON-NUTRIENT CHEMICALS
Cheddar cheese	160
Orange juice	250
Banana	325
Tomato	350
Wine	475
Coffee	625
Beef (cooked)	625

Recommended Dietary Allowances (RDAs) in the United States and the Recommended Nutrient Intakes (RNIs) in Canada. These reference values include Estimated Average Requirement (EAR), RDA, Adequate Intake (AI), and Tolerable Upper Intake Level (UL). To date, several volumes in this series have been published (http://nationalacademies.org/hmd/reports/2000/dietary-reference-intakes-applications-in-dietary-assessment.aspx).

The EAR is the average daily nutrient intake level estimated to meet the requirements of 50% of the healthy individuals in a group, and the RDA is the daily dietary intake level sufficient to meet the nutrient requirements of nearly all (97% to 98%) healthy individuals in a group. RDA is calculated from the EAR; the RDA is the EAR plus two standard deviations (RDA = EAR + 2SD). If sufficient information is not available to establish an EAR and calculate the RDA, an AI level is developed; AI represents the approximate estimates of nutrient intake by healthy people. The UL is the highest level of daily nutrient intake that is not likely to pose any risk of adverse health effects (IOM, 2003). Therefore, nutrient intake levels beyond the UL represent a transition from nutrition to potential toxicity in an exposure-dependent manner.

For adults, the average DRIs (average of values for males and females) for carbohydrate and protein are 130 and 51 g/day, respectively. The acceptable ranges for the source of energy in adults are 45% to 65% from carbohydrate, 10% to 35% from protein, and 20% to 35% from fat (IOM, 2003). The IOM recommendation includes total dietary fiber as a macronutrient and recommends its AI for different age groups in males and females, such as 38 g/day for males and 25 g/day for females, between the age of 19 and 50 years. Dietary fiber is a complex carbohydrate that is primarily a non-calorigenic macronutrient, but it is claimed to have beneficial effects on health and well-being. It is resistant to digestion by the gut enzymes in humans, but can be broken down by gut bacteria.

IMPORTANCE OF THE GASTROINTESTINAL TRACT

Humans consume approximately 1500 g of food and an equal amount of liquid per day; therefore, within a year, humans ingest approximately 550 kg of food (or about 1200 lbs). All these foods are digested, the products of digestion are absorbed from the intestine, and the undigested remains are excreted on a regular basis. The digestive system of all animals has evolved to handle this job efficiently. The gastrointestinal (GI) tract is a large, complex, and dynamic organ with a vast absorptive surface that has been estimated in humans to be 250 square meters or more (Hall, 2011). The digestive system consists of the GI tract (digestive tract), and the liver, pancreas, and gallbladder. The salivary glands, liver, pancreas, and gall bladder all play a direct role in the digestive process. Current understanding of the digestive process demonstrates an important role of the gut microbiome as well. The recently revised estimate of gut microbiome in adult humans is roughly 40 trillion organisms (Sender et al., 2016), which changes the old 10:1 microbe:body cell ratio to roughly 1:1.

Because chemicals and microorganisms from the environment can get direct entry into the GI tract, it has developed the capacity to perform various important functions in addition to digestion. The enterocytes of the intestinal epithelium are capable of extensive metabolism of xenobiotics that gain entry through the GI tract. The ability of the GI tract to metabolize xenobiotics may be second only to the liver, as it possesses a full complement of phase I and phase II xenobiotic metabolizing enzymes and transporters. The GI tract is also an immunologic organ and is constantly exposed to a large number of antigens in food (approximately 88 kg of protein annually), commensal and ingested bacteria. Therefore, the immune system maintains a strong presence at the intestinal mucosal barrier. The immune system of the GI tract is referred to as the gut-associated lymphoid tissue (GALT). It is heavily populated by lymphocytes, macrophages, and other cells that participate in immune responses (Doe, 1989). One cell layer away from these antigens is the lamina propria of the GI tract, which contains the mucosal-associated lymphoid tissue (MALT), comprising lymphocytes and antigen-presenting cells, as well as unique dendritic cells, which interact with dietary antigens and ultimately determine whether an antigen is tolerated or an immune response is initiated (Brandtzaeg, 2010; Vickery et al., 2011).

The combination of a large absorptive surface area and the rich vascularization of the intestine further aids in efficient absorption. The normal rate of blood flow in the portal vein is approximately 1.2 L/h/kg; however, after a meal, there is a 30% increase in blood flow through the splanchnic area (Concon, 1988). Consequently, the substances that affect blood flow also tend to affect the rate of absorption of other materials. An example is alcohol, which tends to increase blood flow to the stomach and thus enhances its own absorption as well as other substances. Lymph circulation is important in the transfer of fats, large molecules, such as botulinum toxin, benzo[*a*]pyrene, 3-methylcholanthrene, and *cis*-dimethylaminostilbene (Chhabra and Eastin, 1984). Lymph has a flow rate of about 1 to 2 mL/h/kg in humans. Tripalmitin has been shown to double the lymph flow rate and therefore double the absorption of materials, such as *p*-aminosalicylic acid and tetracycline (Chhabra and Eastin, 1984). Thus, understanding the changes substances undergo in the GI tract, their possible effect on the GI tract, and whether they are absorbed or affect the absorption of other substances is critical to an understanding of food toxicology and safety assessment (Kotsonis and Burdoch, 2013).

Transporters and Absorption

The constituents of food and other ingesta (e.g., drugs, contaminants, inhaled pollutants dissolved in saliva and swallowed) are physicochemically heterogeneous and, as a result, the intestine has evolved into a relatively impermeable membrane with specialized mechanisms of absorption. Recent progress in transporter research has changed our understanding of the role of various membrane transport proteins in regulating the absorption, distribution, and excretion of food, drugs, and other substances. The role of some transporters in the absorption of various macro- and microingredients in food is shown in Table 27-3. The strategic localization of transporters on the apical versus the basolateral side of the cells is crucial for proper directional transport. It has been known for a long time that hydrophilic molecules need specialized mechanisms for transport through the cell membrane. Even hydrophobic molecules need to be transported by specific transporters in order to maintain a tightly regulated cellular homeostasis. This is contrary to the traditional thinking that assumed that hydrophobic molecules could simply diffuse through the plasma membrane. The transporters may be active transporters or facilitative transporters. In *primary active transport* (1° active), ATP directly provides the energy needed to move a molecule against its concentration gradient. In *secondary active transport* (2° active), the electrochemical gradient of an ion (e.g., Na^+ or H^+), already established through primary active transport, is utilized to move a molecule across the membrane. In *facilitative (facilitated) or passive transport*, transporters passively transport substrates down the concentration gradient from high to low concentration (Choudhuri and Chanderbhan, 2016).

Table 27-3

An Overview of Some Nutritionally Relevant Transporters

TRANSPORTER	*SLC* (GENE) FAMILY DESIGNATION	KNOWN SUBSTRATES
	Sugar Transporters	
SGLT (2° Active) SGLT1—high-affinity but low-capacity glucose transporter that also transports galactose SGLT2—low-affinity but high-capacity glucose transporter that does not transport galactose	*SLC5A*	Glucose, galactose
GLUT (Facilitative) The major glucose transporter across the basolateral membrane	*SLC2A*	Glucose, fructose, myo-inositol, glucosamine, dehydroascorbate
	Amino Acid Transporters	
AA TRANSPORTERS (2° Active or Facilitative depending on the transporter)	*SLC 1A, 6A, 7A, 16A, 36A, 38A, 43A*	Amino acids, monocarboxylates (e.g., lactate, pyruvate)
	Peptide Transporters	
PEPT (2° Active)	*SLC15A*	Dipeptides, tripeptides
	Fatty Acid Transporters	
MCT (2° Active)	*SLC16A*	Short-chain fatty acids (monocarboxylates, e.g., acetate, lactate, pyruvate, butyrate, propionate, succinate)
FATP	*SLC27A*	Long-chain fatty acids
	Nucleoside Transporters	
CNT (2° Active)	*SLC28A*	Nucleosides
ENT (Facilitative)	*SLC29A*	Nucleosides
	Water-Soluble Vitamin Transporters	
SVCT (2° Active)	*SLC23A*	Vitamin C (L-ascorbate)
SMVT (2° Active)	*SLC5A6*	Biotin, pantothenate, α-lipoate
PCFT (2° Active)	*SLC46A1*	Folate, antifolate (e.g., methotrexate)
RFC1 (2° Active)	*SLC19A1*	Folate, antifolate (e.g., methotrexate)
THTR (Facilitative)	*SLC19A2 & SLC19A3*	Thiamine
	Fat-Soluble Vitamin Transporters	
SR-B1		Vitamin D, vitamin E, lutein, lycopene, cholesterol, cholesteryl esters
NPC1L1		Vitamin D, vitamin E, cholesterol
	Other Transporters	
OCTN, CT2 (2° Active or Facilitative depending on the transporter)	*SLC22A*	L-Carnitine
TAUT	*SLC6A6*	Taurine
ZIP	*SLC39*	Metals (e.g., Zn)
ZnT	*SLC30*	Metals (e.g., Zn)
Nramp (Nramp1; Nramp2 also known as DCT1/DMT1)	*SLC11A*	Divalent metals and iron

Once inside the cell, the nutrients exert a multitude of effects from providing energy to regulating specific gene expression and cellular homeostasis, and the survival/death of the cell. Readers are referred to http://slc.bioparadigms.org/ for the detailed classification of the solute carrier (SLC) family of transporters.

Like food, water is absorbed by special means in the GI tract. Fluid transport is a major function of the GI tract, with more than 9 L of fluid being absorbed or secreted across epithelia in human salivary gland, stomach, the hepatobiliary tract, pancreas, small intestine, and colon (Ma and Verkman, 1999). The movement of water across the cell membrane can occur by several mechanisms. The membrane phospholipid bilayer is basically permeable to small polar molecules, and water can slowly permeate the bilayer by simple diffusion. But simple (passive) diffusion is a

slow process that does not account for the transcellular transport of large volumes of water on a daily basis. The general paradigm of water absorption in the GI tract is that water is cotransported along with ions and solutes. For example, Loo et al. (1996) expressed Na^+/glucose cotransporter SGLT1 in *Xenopus* oocyte and demonstrated that the transport of 260 water molecules was directly coupled to each glucose molecule transported. Water is also transported by water channels (aquaporins). Aquaporins are a family of small, integral membrane proteins. The primary function of most aquaporins is to serve as channels in the transfer of water across cell membranes, and in some cases, small solutes. Water transport through aquaporins occurs in response to osmotic gradients created by active solute transport. In addition to water, aquaporins serve in the permeation of small molecules such as glycerol and urea. The mammalian aquaporins are expressed in many cell types involved in fluid transport, including epithelia and endothelia in the kidney, lung, exocrine glands, eye, and GI organs (Takata et al., 2004; Verkman, 2013).

Sometimes a transporter may transport multiple food ingredients as substrates but with vastly different affinities. For example, biotin (vitamin B7) transport is mediated by the Na^+-dependent multivitamin transporter (SMVT; gene *SLC5A6*), which also transports pantothenic acid (vitamin B5) and α-lipoic acid (a metabolic antioxidant) (Prasad and Ganapathy, 2000). The SMVT is a very high affinity transporter of α-lipoic acid, which can inhibit the transport of both biotin and pantothenic acid with an inhibition constant (K_i) of about 5 μM (Choudhuri and Chanderbhan, 2016). Lipoic acid is present in many dietary supplements. It seems logical that separating the intakes of such nutrients/ingredients by several hours might ensure proper absorption from the small intestine. An example of how a drug/xenobiotic transporter may play a protective role from the toxicity of normal food constituents comes from the study of *Abcg2*$^{-/-}$ mice. ABCG2 in humans (Abcg2 in mice), also referred to as BCRP (Breast Cancer Resistance Protein), is an ATP-binding cassette (ABC) transporter that plays an important role in the efflux of many drugs and xenobiotics. Jonker et al. (2002) showed that *Abcg2*$^{-/-}$ mice were extremely sensitive to pheophorbide-a, which is a breakdown product of dietary chlorophyll. These mice had severe phototoxic lesions on light-exposed skin. Because Abcg2 extrudes pheophorbide-a from cells, the lack of Abcg2 activity results in the accumulation of pheophorbide-a in cells. Therefore, low or no Abcg2 activity (due to inherited genetic mutations) may make an organism susceptible to developing diet-dependent photosensitization and even phototoxicity.

FOOD CONSTITUENTS AND GENOTYPIC VARIATIONS: NUTRITIONAL IMPLICATIONS OF INTER-INDIVIDUAL GENETIC DIFFERENCES

There are inter-individual genetic differences in taste preference, food tolerance, metabolism, absorption of food constituents, and other nutrition-related characteristics in human population (Lampe, 2009). The evolution of *Homo sapiens* was intimately associated with adaptive radiation to different environments. Many genotypic variations that conferred selective advantage in an environment were fixed in a population. In terms of food, the impact of selection pressures was reciprocal; that is, just as a genotypic variation could determine the ability to utilize food constituents, food habits could also drive the evolution of traits necessary for nutritional adaptation. However, not all genotypic variants are adaptive in nature; some could even be maladaptive. Certain null alleleic variants can make an individual unable to utilize a food constituent. A classic example discussed in all genetics textbooks is phenylketonuria (PKU), which is an inherited disorder caused by mutations in both alleles of the gene for phenylalanine hydroxylase. Individuals afflicted with PKU have increased levels of the amino acid phenylalanine in the blood because they are not able to metabolize dietary phenylalanine. If PKU is not treated, phenylalanine can build up to harmful levels in the body, causing intellectual disability and other serious health problems.

Many of these genotypic variations are allelic variants created through single nucleotide polymorphisms (SNPs; pronounced *snips*). SNPs and copy number variations (CNVs) are the two common types of heritable variations that are responsible for many apparent inter-individual genetic differences in a population. In the human genome, about 65% of all SNPs involve C→T (transition) mutations. It is thought that many of the SNPs and CNVs can predispose people to disease or influence their response to drugs and xenobiotics. The frequency of occurrence of SNPs in the human genome is about one per 1000 bases, but SNPs that make up about 90% of all human genetic variations occur every 100 to 300 bases in the genome. The inter-individual differences in the ability to produce functional enzymes, transporters, and other proteins that aid in the digestion, transport, and assimilation of nutrients are important determinants of personalized nutrition (Choudhuri, 2009).

Genotypic Variations and the Ability to Utilize Food Constituents

There are a number genotypic variants that determine an individual's ability to utilize nutrients in food—both macro- and micronutrients. The lack of ability to utilize the nutrients often results in mild-to-severe pathological conditions. For example, two polymorphisms in the methylenetetrahydrofolate reductase (*MTHFR*) gene [C677T→Ala222Val (A222V) and A1298C→Glu429Ala (E429A)[1]] are associated with higher homocysteine levels in the blood; the C677T polymorphism being the most common. The C677T variant encodes the thermolabile form of the MTHFR enzyme and it is recognized as the most common genetic cause of hyperhomocysteinemia. The TT homozygous individuals (C677T mutation in both alleles) have mildly elevated homocysteine levels and low-serum folate levels. The frequency of this polymorphism is the highest in Mexico (32%) and the least in Africa (6%). The A1298C does not cause increased homocysteine levels in AC heterozygous or CC homozygous individuals, but combined heterozygosity of A1298C and C677T results in an outcome similar to TT homozygous individuals (van der Put et al., 1998; Wilcken et al., 2003). Carriers of these mutations could be at higher risk of cardiovascular disease (Choudhuri and Chanderbhan, 2016).

Another example of a genotypic variation that impacts the ability to use food ingredients is glutathione *S*-transferase M1 (GSTM1)

[1]A1298C→Glu429Ala means that base #1298 in the open reading frame (ORF) of the cDNA has mutated from Adenine (A) to Cytosine (C). This SNP can also be written as 1298A>C. This A1298C mutation in the ORF has changed the amino acid #429 in the protein from Glutamic Acid to Alanine; hence, Glu429Ala (E429A). The recommendations for designating changes in DNA and protein have been developed by the Human Genome Variation Society, which is an affiliate of the International Federation of Human Genetics Society, and the Human Genome Organization (commonly referred to as HUGO). In the current text, the use of SNP designations is based on that of the original article.

deficiency. Mutations downregulating GSTM1 expression is associated with more rapid excretion of sulforaphane, an isothiocyanate with anti-tumor effects. Because sulforaphane is obtained from cruciferous vegetables, such as broccoli, brussel sprout, and cabbage, individuals with this mutation may not be able to derive the full benefit of consuming cruciferous vegetables. Likewise, polymorphisms in the genes encoding UDP-glucuronosyltransferase (*UGT*) and sulfotransferase (*SULT*) may contribute to variability in phytochemical (e.g., flavonoid) clearance and efficacy (Lampe, 2009; Lampe et al., 2013).

Human milk contains about 200 oligosaccharides that contain 3 to 22 sugar residues (German et al., 2008). These oligosaccharides modulate the microbiota of breast-fed infants (Wang et al., 2015). However, some mothers are deficient in glycosyl transferase enzymes involved in the synthesis of specific oligosaccharides. For example, 2′-fucosyllactose (2′-FL) is a highly abundant oligosaccharide in the milk of most mothers. However, mothers who are deficient in the enzyme α-(1→2)-fucosyltransferase (FUT2) do not produce the 2′-FL in their milk, leading to the nonsecretor phenotype. The human milk oligosaccharides apparently provide protection and enhance the development of the GI and immune systems of breast-fed infants. Thus, genetic differences among mothers can determine a baby's exposure/lack of exposure to specific oligosaccharides from mother's milk (Muñoz et al., 2013).

Lactose malabsorption, commonly also referred to as lactose intolerance,[2] is due to the cessation of expression of the enzyme lactase with age in certain populations. In certain populations the lactase expression is maintained throughout life. Such difference is determined by genotypic difference involving specific SNPs. It has been proposed that the evolution of this trait was the result of nutritional adaptation driven by the food habit (discussed below in detail).

Dietary iron is found in heme and ionic (non-heme) forms and their absorption occurs at the apical surface of the enterocytes of the small intestine by different mechanisms. Heme iron is absorbed by an as yet unidentified, heme receptor (Siah et al., 2006). The metabolism of non-heme iron involves a complex interplay of several proteins, starting from the intestinal divalent metal transporter 1 (DMT1) to the intracellular iron storage protein ferritin. Interestingly, DMT1 is upregulated in iron-deficient diet and it also transports cadmium and lead. Therefore, long-term consumption of iron-deficient diet contaminated with cadmium (such as, the rice in the diet) or lead may result in a significant increase in the body burden of these heavy metal contaminants through food (Park et al., 2002; Bressler et al., 2004). The dysregulation of many of these proteins can cause iron overload in the body and precipitate hemochromatosis. There are several forms of hemochromatosis of which Type 1 hemochromatosis is known as the primary hereditary hemochromatosis. It is an autosomal recessive disorder involving the *HFE* gene on chromosome 6. Two mutations in the *HFE* gene most relevant to the onset of this disease are G845A→Cys282Tyr (C282Y) and C187G→His63Asp (H63D). About 85% to 90% of the affected individuals are homozygous for C282Y mutation (genotype AA) whereas about 5% of the affected individuals are compound heterozygous for C282Y and H63D mutations (genotype: GA at position 845 and CG at position 187) (Siah et al., 2006). Another mutation A193T→Ser65Cys (S65C) localized in the vicinity of H63D also contributes to the etiology of primary hereditary hemochromatosis (Mura et al., 1999). Primary hemochromatosis mainly affects Caucasians of Northern European descent, and is extremely rare in other ethnic groups.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is a genetic disorder that occurs mostly in males because the gene is X-linked. Normally RBCs have a life span of 120 days in the circulation. In individuals affected by G6PD deficiency the life span of RBCs is shortened because of premature hemolysis, resulting in hemolytic anemia. In people with G6PD deficiency, hemolytic anemia can be triggered by certain foods, drugs, and infection. For example, eating fava beans or inhaling pollen from fava plants (*Vicia faba*) can trigger hemolytic anemia. This adverse reaction to fava beans is called favism. Males of Asian, Middle Eastern, or African descent are more prone to this hereditary disorder. Many missense mutations causing single amino acid substitutions of G6PD protein have been described (Vulliamy et al., 1993). Oxidative stress plays an important role in the development of favism. Because G6PD helps in the formation of NADPH, and NADPH helps in the regeneration of GSH from GSSG, G6PD-deficient erythrocytes are NADPH-deficient, high in GSSG, and are consequently prone to oxidative stress-induced damage. Oxidative stress mediates the opening of cation channels that triggers a series of events, such as the entry of Ca^{2+} into the erythrocytes, activation of scramblases, loss of membrane asymmetry, and ultimately hemolysis (Ganesan et al., 2012).

Another example of genotypic variations limiting the uptake of the micronutrient zinc (Zn) comes from the mutations in Zn transporters. At least two zinc transporters, ZIP4 and ZnT2, are now known to be involved in the genetics of zinc deficiency. ZIP4 is an uptake transporter that is involved in intestinal zinc uptake. Mutations in ZIP4, inherited as an autosomal recessive trait, can cause acrodermatitis enteropathica (AE). In contrast, mutations in ZnT2 cause transient neonatal zinc deficiency (TNZD) with symptoms similar to AE but with autosomal dominant inheritance. This is because ZnT2 is responsible for supplying human milk with zinc. The two diseases can be distinguished in affected infants. AE is fatal if zinc is not supplied to the infant after weaning, whereas TNZD is a genetic defect of the mother limiting the supply of zinc in the milk, and therefore the infant usually will obtain enough zinc once weaned (Kasana et al., 2015). Some mutations in ZIP4 and ZnT2 are discussed as follows.

A total of 34 mutations (missense, nonsense, splice-site, and frameshift insertion–deletion mutations) have been reported in the *SLC39A4* gene that codes for the ZIP4 protein. A vast majority of these mutations exist in a homozygous or compound heterozygous state (Küry et al., 2016). Several mutations in mother's *SLC30A2* gene-encoding mutant ZnT2 have also been reported. Heterozygous mutations resulting in His54Arg (H54R) and Gly87Arg (G87R) mutations in ZnT2 lead to a 75% reduction in the secretion of zinc into the human milk. Infants fed on such Zn-deficient milk develop TNZD (Chowanadisai et al., 2006; Lasry et al., 2012). Itsumura et al. (2013) identified two additional missense mutations in the *SLC30A2* gene in a Japanese mother, resulting in a 90% reduction in Zn concentrations in her milk. These were T454C transition in exon 4 causing a Trp152Arg (W152R) mutation, and C887T transition in exon 7 causing a Ser296Leu (S296L) mutation in the ZnT2 protein.

Food Habits Driving Nutritional Adaptation During Evolution

Just as the genotype could determine the ability to utilize food constituents/nutrients, food habits could also drive the evolution of traits necessary for nutritional adaptation. The focus of research

[2]Lactose malabsorption is a common condition caused by reduced expression or activity of lactase in the small intestine. The genetic basis of lactose malabsorption has been established. In contrast, lactose intolerance is less well understood, and could be driven by a number of factors, such as lactase expression, the dose of lactose, intestinal flora, and the sensitivity of the gastrointestinal tract.

in this area has been to identify genetic adaptations to dietary specializations. The obvious candidate genes are those that encode enzymes, which play important roles in nutrient metabolism. To date, the genes coding for amylase (*AMY1*), lactase (*LCT*), and alcohol dehydrogenase (*ADH*) enzymes provide three of the most interpretable examples of genetic adaptations to dietary specializations in human metabolism (Luca et al., 2010).

Starch Digestion An example of how gene CNV may play a role in nutritional adaptation comes from the study by Perry et al. (2007). The alpha-amylase (*AMY1*) gene encodes salivary alpha-amylase enzyme that helps digest starch. Salivary amylase can persist in the stomach and intestine after swallowing, thereby augmenting the enzymatic activity of pancreatic amylase (Luca et al., 2010). There is a direct correlation between the *AMY1* gene copy number and salivary amylase content. When seven different populations were examined for their salivary amylase content and the diploid *AMY1* gene copy number, it was found that the high-starch consuming populations (e.g., agricultural populations of European Americans, Japanese, and Hazda hunter-gatherers) had a higher diploid *AMY1* gene copy number (median 7) compared to the low-starch consuming populations (e.g., Biaka and Mbuti rainforest hunter-gatherers, Datog pastoralists, and Yakut pastoralist and fishing society) (median 5). Further comparison of chimpanzee, Bonobo (an ape), and human *AMY1* genes suggest that (1) the expansion of *AMY1* gene copy number took place in human lineage, suggesting that a shift toward high-starch diet resulted in positive selection of the high CNVs of the *AMY1* gene in the population, and (2) the selection appears to be ongoing even after the evolution of *Homo sapiens* (Choudhuri and Chanderbhan, 2016).

Lactose Digestion An independent evolution of convergent adaptive traits occurred in response to selection pressure related to milk consumption. The lactase gene (*LCT*) is expressed in the intestine, and it produces the enzyme lactase that digests the lactose in milk. Most mammals, including humans, lose the ability to digest lactose with age due to reduced lactase expression. The persistence of lactase expression phenotype, known as lactase persistence (LP), and the continuing ability to digest milk lactose is inherited as a dominant genetic trait. The LP is a common phenotype only in populations with a long history of pastoralism and milk production (Luca et al., 2010). The LP phenotype is high among northern Europeans (more than 90% in Swedes and Danes), decreases across southern Europe and the Middle East (about 50% in Spanish, French, and pastoralist Arab populations), and is low in the African and Asian agriculturalists (about 5% to 20% in West African and about 1% in Chinese). Notably, LP is also prevalent in African pastoralist groups, like the Tutsi (about 90%) and Fulani (about 50%) (Ye and Gu, 2011). Two SNPs, C/T(−13910)[3] and G/A(−22018) identified in the enhancer region of the *LCT* gene are associated with LP phenotype in European populations. The C/T(−13910) is proposed to be the causal regulatory site because of its strong correlation with the LP phenotype (Ye and Gu, 2011). Surprisingly, C/T(−13910) is present in low frequency in a few West African pastoralist populations and absent in others, suggesting the existence of different genetic variants for the LP phenotype in Africans. The genetic variants determining the LP phenotype in Africans were identified through a genotype–phenotype association study by Tishkoff et al. (2007). The authors identified three SNPs [G/C(−14010), T/G(−13915), and C/G(−13907)] that are associated with the LP phenotype, as confirmed by enhanced in vitro transcription of the alleles containing these SNPs. These SNPs originated on different haplotype backgrounds compared to that of the European C/T(−13910) SNP. Subsequently, Enattah et al. (2008) identified two new population-specific SNPs determining the LP phenotype among Middle Easterners: T/G(−13915) within the −13910 enhancer region and a synonymous T/C(−3712) SNP in exon 17 of the *MCM6* gene. It is interesting to note that the *MCM6* gene, which is a different gene, contains some of the regulatory regions controlling *LCT* gene expression. The absence of the European C/T(−13910) SNP in these populations was also confirmed by the authors. Because the SNPs responsible for the LP phenotypes are different in geographically isolated populations, it suggests the independent evolution of convergent adaptive traits in response to similar selection pressure (milk consumption).

Alcohol Metabolism Natural selection has led to metabolic adaptation that is protective of alcohol overconsumption related to fermentation of food. Ethanol is oxidized to acetaldehyde by alcohol dehydrogenase (ADH), and acetaldehyde is subsequently oxidized to acetic acid by aldehyde dehydrogenase (ALDH). The metabolism of ethanol varies widely among individuals due to genetic variations in these two genes. One of the best-studied polymorphisms influencing ethanol metabolism is *ADH1B* Arg47His (Peng et al., 2010). The *ADH1B*47His* allele (previously called *ADH2*2*) causes enhanced catalytic activity, resulting in an increased metabolism of ethanol, and increased blood levels of acetaldehyde. If acetaldehyde is not metabolized rapidly by ALDH, chronic tissue exposure to acetaldehyde could result in significant adverse consequences including cancer. Therefore, ALDH deficiency, which is seen among East Asians, together with an increased catalytic activity of ADH results in an increased blood level of acetaldehyde. This causes flushing, intolerance, and discomfort associated with alcohol drinking. Such individuals are most likely to avoid alcohol. Therefore, the *ADH1B*47His* allele indirectly serves to protect from alcoholism (Li et al., 2007). A global investigation of the *ADH1B*47His* allele frequency shows a strong geographic distribution; it is dominant in East Asian populations, but rare in European and African populations. The regionally restricted enrichment of this allele in southern China and the adjacent areas suggests positive selection. Molecular dating suggests that the emergence of this allele coincides with the origin of rice domestication in East Asia, and that there is a strong correlation between *ADH1B*47His* frequency and the age of rice domestication (Peng et al., 2010). It has been proposed that the rise of *ADH1B*47His* allele frequency was an adaptation to rice domestication and the subsequent production and consumption of fermented food and/or beverages. Because *ADH1B*47His* is involved in protection from alcohol overconsumption-related adverse effects, the fixation of this allele was favored by natural selection (Peng et al., 2010).

FOOD CONSTITUENTS AND REGULATION OF GENE EXPRESSION

One of the earliest examples of nutrient-mediated modulation of gene expression came from the discovery of the lactose operon in *Escherichia coli*. Growing *E. coli* in lactose instead of glucose led to the de novo transcription and expression of three enzymes:

[3]C/T(−13910) means that base #13910 upstream of the transcription start site in the gene (i.e., to the left of the transcription start site in the linear sequence) has mutated from C to T. This can also be represented as −13910C>T or C−13910T or C/T_{-13910}. Therefore, SNP notation with a "−" sign represents a mutation in the regulatory region of the gene. Depending on the distance from the transcription start site, the mutation may fall in the proximal or distal promoter, or further upstream in the enhancer. Obviously −13910 position falls in the enhancer region of the gene.

β-galactosidase, *trans*-acetylase, and permease that are all involved in the uptake and utilization of lactose as the carbon source. Likewise, in higher eukaryotes nutrients such as glucose, amino acids, fatty acids, as well as vitamins and minerals are known to regulate gene expression (Choudhuri and Chanderbhan, 2016).

Carbohydrates and Gene Expression

Glucose homeostasis is tightly regulated in the body to meet the energy demands during the starvation/feeding cycle in animals. Red blood cells and the brain primarily rely on a direct supply of glucose as their fuel source. Therefore, for most genes regulated by a rich carbohydrate diet, the induction or inhibition of their mRNAs is substantial and relatively rapid, and is reversible once the carbohydrate availability decreases. Both insulin and glucose contribute to the coordinated regulation of carbohydrate and lipid metabolism in the liver (Vaulont et al., 2000; Dentin et al., 2005).

Fasting causes low-insulin levels, and activates glucose production and lipolysis. In contrast, feeding a carbohydrate-rich diet after fasting activates fat synthesis by enhancing the rate of fatty acid synthase transcription (Fukuda et al., 1999). Many enzymes involved in carbohydrate metabolism are induced in the liver and other tissues by a diet high in carbohydrates. For example, Iynedjian et al. (1987) demonstrated that in adult rats, *glucokinase* mRNA was low during fasting but it increased more than 50-fold above the fasting level within 6 hours of an oral glucose load, and the mRNA level returned toward basal values by 18 hours after refeeding. A high carbohydrate (65% sucrose) diet also induces *L-type pyruvate kinase* (*L-PK*) and *aldolase B* mRNAs in rats (Weber et al., 1984). In livers from starved rats, *L-PK* mRNA was practically undetectable. A carbohydrate-rich diet increased both mRNA concentrations, with a maximum being between 12 and 18 hours, and the increase being about 4 to 8 times for *aldolase B* mRNA and 40 to 100 times for *L-PK* mRNA. Transcription was maximal at 12 hours after refeeding, decreasing to 10% of maximum at 72 hours. The level of transcribed *L-PK* mRNA remained constant at 50% of maximum for at least 120 hours (Vaulont et al., 1986). Glucose also induces the expression of glucose transporters and lipogenic enzymes, such as acetyl CoA carboxylase (ACC) (Pape et al., 1988) and fatty acid synthase (FAS) (Paulauskis and Sul, 1989), and represses the expression of genes of the gluconeogenetic pathway, such as phosphoenolpyruvate carboxykinase (PEPCK) (Kahn et al., 1989). Both insulin and glucose can independently repress *PEPCK* gene expression. Normally, PEPCK expression is induced by glucagon but is dominantly inhibited by glucose-induced increases in insulin secretion upon feeding (Kahn et al., 1989).

Based on a number of observations, Mourrieras et al. (1997) proposed that *glucose-6-phosphate (G6P) is the most likely signaling molecule regulating the glucose-induced transcription of the target genes*. The conversion of glucose to G6P is carried out by glucokinase, whose expression is strongly activated by insulin. Glucose-6-Phosphatase (G6Pase), the enzyme that breaks down G6P to release glucose, is active in the liver, kidneys, and intestines, and is the main regulator of glucose production in the liver. Insulin reduces G6Pase expression (mRNA and protein levels) in the fed and refed state where insulin levels are elevated (Argaud et al., 1996). In contrast, a low-glucose level dramatically increases G6Pase expression (mRNA and protein levels) so that more glucose can be obtained from the glycogen stores to meet the cellular energy need. Therefore, in a fed and refed state, when both insulin and glucose levels are high, insulin exerts a dominant negative effect. The dominant negative effect of a high-insulin level on glucagon-mediated *PEPCK* gene expression and *G6Pase* gene expression is yet another testimony of insulin's central role in regulating carbohydrate metabolism.

Two transcription factors—the sterol regulatory element (SRE)-binding protein 1c (SREBP-1c) and the carbohydrate response element (ChRE)-binding protein (ChREBP)—play crucial roles in insulin- and glucose-mediated transcriptional regulation of genes involved in carbohydrate metabolism (Foufelle and Ferré, 2002; Dentin et al., 2005; Shankar et al., 2010).

SREBP-1c is a major mediator of insulin action on hepatic glucokinase and lipogenic gene expression. It is rapidly and robustly induced by a carbohydrate-rich diet (resulting in a high-insulin level) and downregulated by fasting (resulting in a low-insulin level). The expression of *SREBP-1c* gene itself is under the control of the nuclear receptor transcription factor liver-X-receptor (LXR) (Espenshade, 2006). For nuclear receptors (NRs) that form heterodimers with the retinoid-X-receptor (RXR), the NR–RXR (in this case LXR-RXR) heterodimer binds to the corresponding response element (NR-RE; in this case LXRE) in the promoter of the target genes. The induced SREBP-1c binds to the SREs in the promoter of the target genes, such as *glucokinase*, *ACC*, *FAS* (Dentin et al., 2005). Fig. 27-1 shows the relationship between the glycolytic and lipogenic pathways.

The ChREBP is another important regulator that mediates the effects of glucose; it is predominantly expressed in the liver, kidney, and white and brown adipose tissue. ChREBP forms a heterodimer with Max-like protein X (Mlx) that binds to the carbohydrate response element (ChRE) located in the promoters of glucose target genes, such as the *L-PK*, *FAS*, and *ACC*. The ChREBP–Mlx complex is able to discriminate between the E-box sites that are glucose-responsive and those that are not (Stoeckman et al., 2004). Fig. 27-2 shows possible signaling pathways for transcriptional regulation of target genes in the liver mediated by glucose and insulin.

Studies in humans with high- and low-carbohydrate diets showed differential gene expression in subcutaneous fat as well. In individuals fed a rye-pasta diet (low postprandial insulin response), 71 genes showed decreased expression and none showed increased expression. In contrast, in individuals fed an oat–wheat–potato diet (high postprandial insulin response), 62 genes showed increased expression and none showed decreased expression (Kallio et al., 2007). Two of the noteworthy downregulated genes were the hormone-sensitive lipase (*HSL*) gene and the transcription factor *TCF7L2* gene. Downregulation of HSL, which is a key enzyme in the release of fatty acids from adipose tissue, is associated with resistance to genetic or diet-induced obesity. The transcription factor TCF7L2 is the strongest known genetic predictor of type 2 diabetes. In humans, the stable but differential expression pattern of many genes involved in carbohydrate metabolism may be rooted in geographic ancestral lineage (Schisler et al., 2009).

Amino Acids and Gene Expression

On an average, the daily protein turnover (synthesis and breakdown of proteins) in humans is more than 300 g/day; about half of the daily protein turnover comes from protein synthesis (Waterlow, 1984; Poortmans et al., 2012). About 75% of the amino acids are utilized for the resynthesis of tissue proteins. Unlike carbohydrates and fats, excess amino acids cannot be stored, but are degraded primarily in the liver. Most of the nitrogen in amino acids is converted to urea and excreted, while the carbon skeletons are either oxidized to form carbon dioxide and water or utilized for gluconeogenesis and ketogenesis.

Amino acid availability regulates the expression of many genes both in vivo and in vitro. Some examples of genes upregulated by

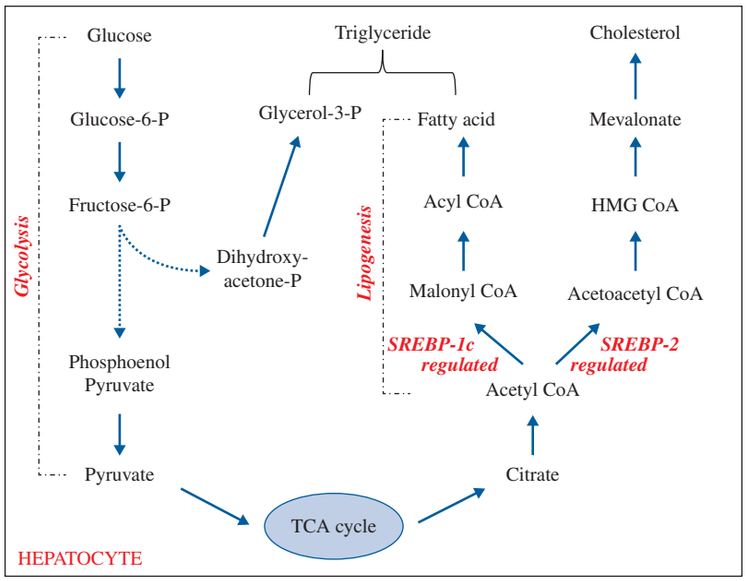

Figure 27-1. *The liver is the major site of carbohydrate metabolism (glycolysis and glycogen synthesis) and fatty acid synthesis (lipogenesis).* The precursor of fatty acid synthesis is acetyl CoA. The SREBP-1c preferentially regulates genes involved in de novo lipogenesis, but SREBP-2 preferentially regulates genes involved in cholesterol synthesis and uptake, at least in the liver.

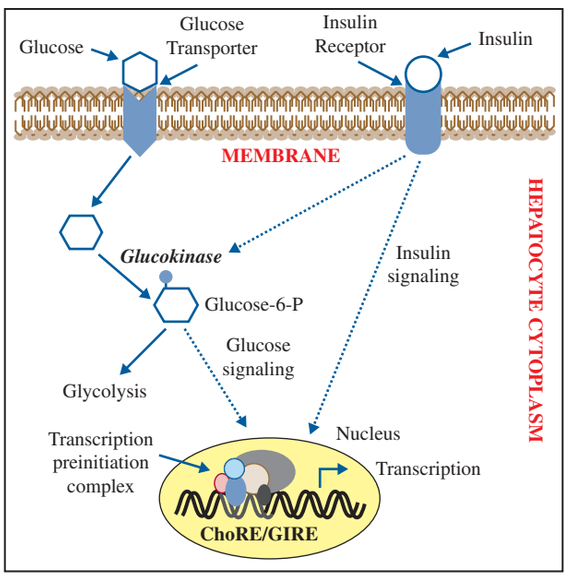

Figure 27-2. *Transcriptional regulation by glucose and insulin signaling in the liver.* Glucose-6-phophate is the most likely signaling molecule regulating glucose-induced transcription, and its formation is an important step in glucose-signaling pathway. Insulin-signaling pathway may involve insulin-responsive transcription factor SREBP-1c.

amino acid starvation include the enzymes of amino acid synthesis pathway (e.g., asparagine synthetase, glutamine synthetase), enzymes of the urea cycle (e.g., argininosuccinate synthetase), the rate-controlling enzyme in polyamine biosynthesis pathway (e.g., ornithine decarboxylase), transporters (e.g., sodium-coupled neutral amino acid transporter SNAT2, cationic amino acid transporter CAT1, amino acid transporter ATA2), ribosomal proteins (e.g., L17, L35, S13, and S25), transcriptional activator proteins, such as CCAAT/enhancer-binding protein (C/EBP) and C/EBP homologous protein (CHOP), insulin-like growth factor-binding protein-1 (IGFBP-1), and proto-oncogenes (jun and myc) (Kilberg et al., 1994, 2012; Fafournoux et al., 2000; Jousse et al., 2004; Brasse-Lagnel et al., 2009).

Overexpression of IGFBP-1 (e.g., in transgenic mice) causes growth defect. Growth defect is also seen in amino acid deficiency. Consistent with these facts was the finding that strong induction of *IGFBP-1* mRNA in the liver was seen following feeding rats with a low-protein diet for 10 days. Amino acid starvation has also been reported to induce *IGFBP-1* mRNA in cultured cells (Jousse et al., 2004). Amino acid supplementation results in the upregulation of a number of genes. For example, a high concentration of tryptophan enhances the expression of collagenase and tissue inhibitors of metalloproteinases. The expression of argininosuccinate synthetase and ornithine decarboxylase, which are induced by amino acid starvation, is also upregulated in response to high amino acid supplementation. The majority of the mRNA increase by amino acid starvation or supplementation is through an increase in de novo transcription (mRNA synthesis), but mRNA stabilization also plays important roles. For example, the increase in *CHOP* mRNA, at least in part, involves mRNA stabilization. High glutamine concentration induces the accumulation of *argininosuccinate synthetase* mRNA in isolated hepatocytes. Similarly, high asparagine concentration induces *ornithine decarboxylase* mRNA expression primarily by post-transcriptional stabilization of the mRNA, but also by stimulating the synthesis and suppressing the degradation of ornithine decarboxylase protein (Fafournoux et al., 2000). The translation of mRNAs of some of these amino acid–regulated genes is initiated through internal ribosomal entry sites (IRES).[4]

[4]IRES facilitate cap-independent translational initiation, and are located at the 5′-untranslated region of certain "survival" mRNAs whose expression is upregulated during severe cellular stress. Many viral mRNAs employ the same mechanism to hijack the host's translation machinery.

The current knowledge on the amino acid regulation of gene expression has developed mostly from detailed studies on the upregulation of two genes, *CHOP* and asparagine synthetase (*AS*), in response to amino acid starvation. *It may be emphasized here that cellular stressors like nutrient and energy deprivation activate autophagy, which is the primary catabolic program.*

The *CHOP* gene expression is strongly induced by cellular stress, such as oxidative stress, DNA damage, and amino acid starvation. CHOP is a nuclear protein related to the CCAAT/enhancer-binding protein (C/EBP) family of transcription factors. Leucine limitation in human cell lines results in the induction of *CHOP* mRNA and protein in a dose-dependent fashion (Averous et al., 2003). The *CHOP* gene promoter contains the amino acid response element (AARE), which binds in vitro the activating transcription factor 2 (ATF-2) under both starved and unstarved conditions. The expression of *CHOP* mRNA during amino acid starvation is mediated by ATF-2 and ATF-4 (Bruhat et al., 2000; Jousse et al., 2004). The expression of *CHOP* mRNA is also induced by endoplasmic reticulum (ER) stress response (ERSR), also known as unfolded protein response (Patil and Walter, 2001), and is mediated by the ER stress response element (ERSRE)-binding protein ATF-6.

Asparagine synthetase (AS) is responsible for the biosynthesis of asparagine from aspartate and glutamate. It is ubiquitously expressed in most mammalian cells. The transcription of the *AS* gene is also increased in response to both amino acid and glucose starvation, the latter resulting in an ERSR as discussed above. The *AS* gene contains five specific *cis*-elements: three GC boxes (GC-I, GC-II, and GC-III) and two nutrient-sensing response elements (NSRE-1 and NSRE-2) (Leung-Pineda and Kilberg, 2002). All three GC boxes are required for basal transcription and also for the maximal induction of the *AS* gene by amino acid limitation. The genomic unit containing both NSRE-1 and NSRE-2 is called nutrient-sensing response unit (Jousse et al., 2004). Even though amino acid starvation does not cause ER stress (unfolded protein response), the amino acid starvation response pathway and the ER stress pathway appear to closely overlap. This may be due to the involvement of some common transcriptional *trans*-activators that are involved in both pathways, such as ATF-4 (Jousse et al., 2004).

The amino acid deficiency response involves a number of signaling pathways that include many proteins, but the central pathway of general control nonderepressible 2 (GCN2)–eukaryotic initiation factor eIF2–ATF4 appears to be involved in all tissues (Kilberg et al., 2012; Choudhuri and Chanderbhan, 2016).

Fatty Acids and Gene Expression

Fatty acids and their acyl-CoA derivatives serve many biological functions within the cell. They serve as metabolic energy sources, substrates for membranes, signaling molecules for metabolic regulation, and regulators of gene expression. Fatty acid regulation of gene transcription occurs in unicellular as well as complex organisms (Duplus et al., 2000).

While controversy still exists regarding the contribution of passive diffusion versus protein-mediated fatty acid transport, both processes are now widely accepted (Kalant and Cianflone, 2004). A completely passive diffusion of fatty acids across the plasma membrane is not conducive to maintaining cellular homeostasis. The uptake of fatty acid across the plasma membrane is mediated by distinct transport proteins (Table 27-3). Once within the cell, most fatty acids are non-covalently bound to fatty acid-binding proteins (FABPs). FABPs are involved in reversibly binding intracellular hydrophobic ligands, and trafficking them throughout cellular compartments, including the peroxisomes, mitochondria, endoplasmic reticulum, and nucleus (Smathers and Petersen, 2011).

The regulation of gene expression by fatty acids is dictated by the type, quantity, and the duration of exposure to dietary fats. Among short-chain fatty acids (SCFAs), such as acetate, propionate, and butyrate, the effects of butyrate on gene expression have been studied by many laboratories. Butyrate is produced by anaerobic bacterial fermentation of dietary fibers. It was shown by the mid-1970s that sodium butyrate halts DNA synthesis, arrests cell proliferation, alters cell morphology, and increases or decreases gene expression (Prasad and Sinha, 1976). The observation that butyrate increased the level of acetylated histones in cultured HeLa and Friend erythroleukemic cells was a turning point in understanding the molecular mechanisms of action of butyrates in gene regulation (Davie, 2003). Butyrates were found to increase gene expression by inhibiting histone deacetylase activity, thereby increasing histone acetylation, which promotes transcriptional activation (Davie, 2003).

A large number of studies investigating the role of fatty acids on gene expression have focused on the long-chain fatty acids (LCFAs). Analyses of fatty acid regulation of gene expression have focused on several possible mechanisms, including peroxisome proliferator-activated receptor (PPAR) and prostanoid-regulated processes (Jump and Clarke, 1999). PPAR is a ligand-dependent transcription factor that heterodimerizes with RXR. Three different PPAR subtypes have been cloned—PPARα, PPARβ (or δ), and PPARγ. All three forms of PPARs bind polyunsaturated fatty acids (PUFAs), such as arachidonic acid (ARA), docosahexanoic acid (DHA), and others. In addition to PUFAs that are bona fide PPAR ligands, numerous fatty acid-derived compounds showing a structural resemblance to fatty acids, such as acyl-CoAs, oxidized fatty acids, eicosanoids, endocannabinoids, and phytanic acid, have also been shown to activate PPARs (Clark, 2002).

Surprisingly, circulating free fatty acids (FFAs) that primarily originate from adipose tissue lipolysis (so-called *old fat*) cannot activate PPARα in the liver. In contrast, dietary and endogenously synthesized fatty acids (so-called *new fat*) can. This difference may be related to the existence of (as yet unknown) differential signaling properties between the two forms of FFAs. However, the plasma FFAs (the *old fat*) can activate hepatic PPARγ (Georgiadi and Kersten, 2012).

Studies in rodents demonstrated that PPARα mediates the effects of dietary fatty acids on hepatic gene expression (Choudhuri and Chanderbhan, 2016). The importance of PPARα in overall glucose and fatty acid homeostasis was demonstrated by the observations that PPARα-knockout mice lack the ability to increase fatty acid oxidation during periods of food deprivation and they develop characteristics of adult-onset diabetes, including fatty livers, elevated blood triglycerides, and hyperglycemia (Clark, 2002). *Because PPARα plays a pivotal role in both fatty acid and glucose metabolism, it was proposed to be a "master switch" transcription factor that is targeted by PUFAs to coordinately suppress genes encoding the enzymes of lipid synthesis and induce genes encoding the enzymes of fatty acid oxidation and thermogenesis* (Clark, 2002). It should be borne in mind, however, that peroxisome proliferation is a rodent-specific response mediated by PPARα. Although humans have a functional PPARα, its expression and ligand-binding affinities are different from that of mouse PPARα.

The PPARs play a critical physiological role as lipid sensors and regulators of lipid metabolism (Rogue et al., 2010). The major groups of target genes for the PPARs are genes involved in lipid and glucose metabolism. PPARα exerts its effects on the liver and muscle, whereas PPARγ exerts its effects on the adipose tissues and tumor cells. PPARα ligands include both ω-3 and ω-6 PUFAs, but ω-3 PUFAs seem to be more potent (Price et al., 2000). PPARγ is expressed at the highest level in adipose tissue whereas

its expression in the liver is low, being only 10% to 30% of the level in adipose tissue in both mice and humans. Prostaglandin PGJ_2 is a PPARγ ligand; it binds and activates PPARγ. The effects of PPARγ on lipid metabolism are mainly mediated by genes expressed in adipocytes.

Fatty acids also regulate the expression of various transcription factors, such as SREBP-1c, LXR, farnesoid-X-receptor (FXR, the bile acid–activated nuclear receptor), hepatic nuclear factor 4α (HNF-4α), and NF-κB (Georgiadi and Kersten, 2012), thus regulating the expression of the target genes of these transcription factors. Mammalian cells produce several isoforms of SREBPs. The importance of SREBP-1a, SREBP-1c, and SREBP-2 in regulating the expression of genes relevant to carbohydrate and lipid metabolism has been studied more extensively. SREBP-1a and -1c are the products of alternative splicing but SREBP-2 is encoded by a different gene (Hua et al., 1995). Unlike typical transcription factors, SREBPs are synthesized as integral membrane proteins localized in the endoplasmic reticulum. The N- and the C-terminal domains are cytosolic (Fig. 27-3). *The N-terminal domain of the SREBP is the actual transcription regulatory part of the protein and it contains a basic helix–loop–helix (bHLH)–Zip domain*. This domain is cleaved from the membrane by a sterol-regulated protease and allows it to enter into the nucleus. In the nucleus, this transcription regulatory bHLH-Zip domain binds to the enhancer sequences known as the sterol response elements (SREs) of the lipogenic genes, and activates transcription (Ye and DeBose-Boyd, 2011). The proteolytic pathway that liberates the N-terminal bHLH-Zip domain from membranes in response to intracellular levels of cholesterol and fatty acids is known as the SREBP pathway (Brown and Goldstein, 1997).

Dietary PUFAs inhibit hepatic lipogenesis through inhibition of both SREBP-1c and SREBP-2, in particular SREBP-1c (Georgiadi and Kersten, 2012). Interestingly, the ω-3 long-chain PUFAs (e.g., EPA and DHA) and the ω-6 PUFA (e.g., ARA) have far more inhibitory capacity on SREBP than do the shorter chain unsaturated fatty acids (e.g., 18:1 oleic acid, 18:2 linoleic acid), and saturated fatty acids have almost no effect on SREBP (Georgiadi and Kersten, 2012; Choudhuri and Chanderbhan, 2016). The SREBP-1c preferentially activates genes involved in de novo lipogenesis, but SREBP-2 preferentially activates genes involved in cholesterol synthesis and uptake, at least in the liver (Fig. 27-1). Because PUFAs antagonize LXR, PUFAs inhibit the transcription of LXR-regulated genes, such as *SREBP-1a* and *SREBP-1c*, in humans (Hannah et al., 2001).

Dietary fatty acids can also regulate the expression of proteins associated with micronutrient metabolism. It is well known that vitamin A absorption in the intestine is stimulated by the presence of fat. The modulation of intestinal vitamin A absorption is the result of a dietary fat-inducible cellular retinol-binding protein II (CRBPII), which plays a pivotal role in the intestinal absorption and metabolism of retinol and β-carotene. In mice, unsaturated fatty acids (e.g., oleic, linoleic, and α-linolenic acids) enhance *CRBPII* mRNA levels, whereas medium-chain fatty acids and saturated fatty acids have little effect. Consistent with this finding, feeding a fat-free diet repressed *CRBPII* mRNA accumulation in the small intestine by 50% within a day, and this low level was sustained over the following 9 days. The molecular mechanism of such dietary fatty acid regulation was shown to involve PPARα (Takase et al., 2000).

Vitamins and Gene Expression

Like the macronutrients (protein, carbohydrate, and fat), micronutrients (vitamins and minerals) can also modulate gene expression. There are several publications discussing the potential role of vitamins in regulating gene expressions. These studies primarily relied on microarray to investigate global gene expression profiling; hence, these findings need to be tested more comprehensively in order to establish the causality. The following discussion focuses on two examples, vitamins A and D.

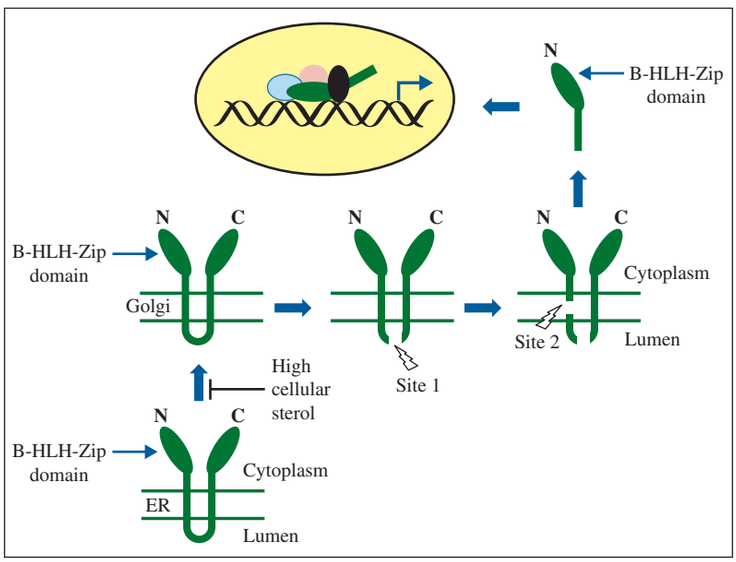

Figure 27-3. *The N-terminal domain of SREBP is the actual transcription regulatory part of the protein and it contains a basic helix–loop–helix (bHLH)–Zip domain.* The precursor of SREBP is synthesized in the endoplasmic reticulum (ER), where it is in complex with another protein, the SREBP cleavage activating protein (SCAP). SCAP contains a sterol sensory domain. In low intracellular sterol concentration, SCAP helps in the translocation of SREBP to the Golgi. This translocation is prevented when the intracellular sterol concentrations are high. Once in Golgi, the SREBP undergoes two proteolytic cleavage steps to release the mature, biologically active transcription factor that translocates to the nucleus. The nuclear SREBP binds to the sterol response element (SRE) in the promoter/enhancer regions of target genes to activate transcription.

Vitamin A-mediated regulation of gene expression is a well-known example of direct gene regulation by micronutrients. Retinoic acid, a bioactive form of vitamin A, is a ligand for the nuclear retinoic acid receptor (RAR). Ligand-activated RAR heterodimerizes with RXR; the RAR–RXR complex binds to the cognate retinoic acid response element (RARE) in the regulatory region of the target genes and regulates gene expression. As mentioned above, PEPCK-catalyzed reaction is the rate-limiting step of gluconeogenesis in animals. The expression of *PEPCK* gene is a target of retinoic acid. Retinoic acid plays an important role in development, but high levels of retinoic acid exposure can be teratogenic to the developing embryo. Thus, it is imperative that retinoic acid targets many genes including the developmentally important homeobox (*Hox*) genes, such as *Hoxa1, Hoxb1, Hoxb4,* and *Hoxd4*. All the target genes harbor RARE (Rhinn and Dollé, 2012). Dietary vitamin A levels can also modulate the expression of genes encoding insulin-like growth factor I (IGF-I), IGF-I receptor (IGF-IR), and insulin receptor (IR) in many different tissues. Serum IGF-I concentrations and tissue *IGF-I* mRNA are downregulated by vitamin A deficiency (Choudhuri and Chanderbhan, 2016).

The model of vitamin D (1,25-dihydroxyvitamin D_3)-mediated gene expression involves similar steps of events as for vitamin A, that is, vitamin D binding-mediated activation of vitamin D receptor (VDR), formation of VDR–RXR complex, its binding to VDRE, and modification of transcriptional output. Genome-wide mapping of vitamin D receptor binding revealed that vitamin D could influence over 200 genes, highlighting links to disease states (Ramagopalan et al., 2010). Vitamin D plays an important role in regulating genes involved in bone remodeling and the maintenance of bone health, such as *VDR*, *TNFSF11*, *LRP5*, *CBS*, and *CYP24a1*.

Vitamin D and the Genetics of Bone Remodeling

During bone remodeling osteoclasts resorb old bone tissue, osteoblasts deposit new bone tissue, and some osteoblasts that become trapped within the bone matrix differentiate into osteocytes. When the two functions are out-of-balance, bone health is affected. For example, when osteoclasts remove more bone than osteoblasts can deposit, the result is osteoporosis. In contrast, if osteoblasts deposit more bone than osteoclasts can remove, the result is osteopetrosis (hyper dense bones). By regulating the *VDR* gene, vitamin D regulates a wide variety of target genes that contain the VDRE. The *VDR* gene is highly expressed in osteoblasts, terminally differentiated osteocytes and probably in osteoclasts as well. The *TNFSF11* gene produces the protein RANKL that regulates osteoclast differentiation, function, and activation. In normal bone remodeling, the RANKL (ligand) is secreted by osteoblasts and binds to the RANK receptor on both osteoclast precursor and mature osteoclast cells. The RANK–RANKL interaction triggers cellular signaling events that trigger osteoclast differentiation, function, and activation. This can be inhibited by osteoprotegerin (OPG), which is produced by osteoblasts and stromal cells and acts as a decoy receptor that sequesters RANKL. Sequestration of RANKL by OPG inhibits the differentiation and activation of osteoclasts. Evidently, the RANKL/OPG ratio acts as an important determinant of bone mass and skeletal integrity by regulating the balance between bone resorption and bone deposition processes. This is also demonstrated in animal models—RANK-null ($RANK^{-/-}$) and OPG-null ($OPG^{-/-}$) mice. While RANK-null mice develop osteopetrosis-like conditions (Dougall et al., 1999), OPG-null mice develop osteoporosis-like conditions (Bucay et al., 1998). The *LRP5* gene encodes LRP5 protein that regulates osteoblast proliferation and differentiation. A loss-of-function mutation in *LRP5* gene causes a decrease in bone mass and osteoporosis, whereas a gain-of-function mutation causes drastic increases in bone mass. The *CBS* gene encodes the enzyme cystathionine β-synthase that converts homocysteine to cystathionine, which is an intermediate in the synthesis of cysteine. High homocysteine levels are a risk factor for osteoporotic fracture. Thus, individuals with cystathionine β-synthase deficiency that results in a reduction in the enzyme activity are prone to osteoporosis (Kruger et al., 2003).

Mencej-Bedrac et al. (2009) reported certain SNPs in the human *VDR*, *OPG*, and *TNFSF11* genes that are associated with bone mineral density. These SNPs predispose the carriers to osteoporosis. Vitamin D is inactivated by the vitamin D 24-hydroxylase, which is encoded by the *CYP24A1* gene. Because vitamin D upregulates the expression of *CYP24A1,* it autoregulates its own inactivation. Vitamin D also regulates a network of genes involved in bile acid metabolism in the colon, the degradation of xenobiotic compounds in several tissues, the differentiation of keratinocytes in skin, the development and cycling of dermal hair follicles, and the functions of key cell types involved in both innate and adaptive immunity (Pike and Meyer, 2010; Pike et al., 2014).

Some vitamins may also regulate gene expression through epigenetic modification of the chromatin. For example, using Jurkat lymphoma cells, Gralla et al. (2008) demonstrated that when biotin concentration in Jurkat cells was high because of high levels of biotin supplementation in the media, the lysine 12 of histone H4 (H4K12) at the SMVT promoter had high levels of biotinylation (H4K12Bio). Biotinylation of histone H4 is a transcription repressing modification. Therefore, high levels of intracellular biotin downregulated the expression of SMVT (by 86%) and resulted in a significant decrease in further biotin uptake. Thus, biotin may autoregulate its own intracellular concentration by regulating its own uptake through epigenetic regulation of SMVT.

Minerals and Gene Expression

In recent years, several nutrigenomics studies investigated global changes in gene expression by a number of minerals. The changes in gene expression profiles by the same mineral reported in different studies are not the same. Therefore, these findings are yet to be interpreted for their overall biological relevance to be able to develop a coherent narrative. The following discussion focuses on iron.

Dietary non-heme ferric iron Fe(III) is first reduced by enterocyte membrane-bound ferrireductases into ferrous Fe(II) form. The apical transporter divalent metal transporter 1 (DMT1) transports Fe(II) from the intestine into the enterocytes, thus helping in non-heme iron absorption. Heme iron is taken up by enterocytes by an as yet undefined mechanism. The Fe(II) is translocated through the enterocyte and is exported into the circulation by the basolateral exporter ferroportin. *Ferroportin is the only iron export protein known*. During export, Fe(II) is oxidized by hephaestin, which is a membrane-bound ferrooxidase. Thus, hephaestin is necessary for effective iron transport from enterocytes into the circulation. In the circulation, Fe(III) binds to plasma transferrin (Tf) to be distributed throughout the body, and taken up primarily by the liver. In the liver, the Fe(III)–Tf complex binds to the membrane transferrin receptor (TfR). The Fe(III)–Tf–TfR complex is endocytosed inside the cell. The acidic pH of the endosome releases the Fe(III), which is again reduced to Fe(II) by the intracellular ferrireductase STEAP3 (Fig. 27-4). The intracellular iron storage is regulated at multiple levels.

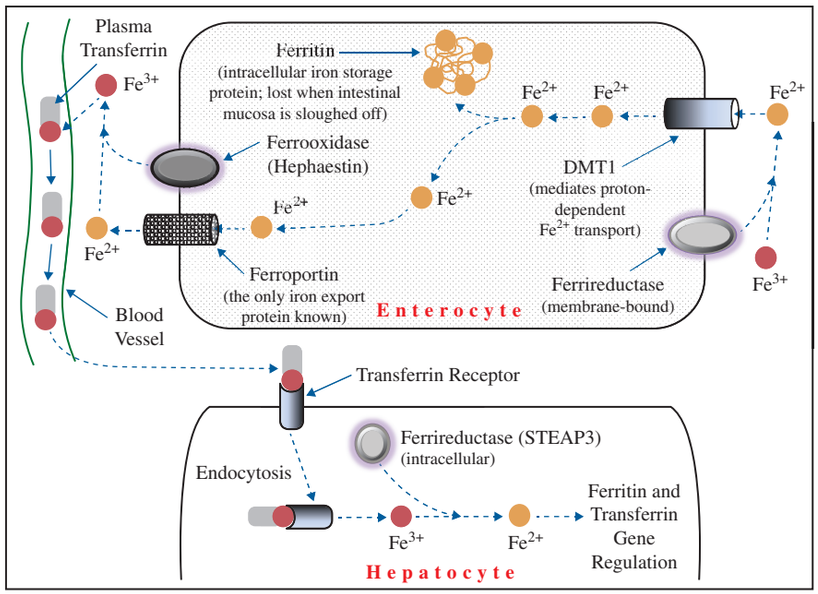

Figure 27-4. *The transport of dietary iron from the intestine to the liver.* Non-heme ferric iron Fe(III) is first reduced by enterocyte membrane–bound ferrireductases into ferrous Fe(II) form. The apical transporter divalent metal transporter 1 (DMT1) transports Fe(II) into the enterocytes. The Fe(II) is translocated through the enterocyte and is exported into the circulation by the basolateral exporter ferroportin. During export, Fe(II) is oxidized by hephaestin, which is a membrane-bound ferrooxidase. In the circulation, Fe(III) binds to plasma transferrin to be distributed throughout the body, and taken up primarily by the liver. In the liver, the Fe(III)–Tf complex binds to the membrane transferrin receptor (TfR). The Fe(III)–Tf–TfR complex is endocytosed inside the cell. The acidic pH of the endosome releases the Fe(III), which is again reduced to Fe(II) by the intracellular ferrireductase STEAP3.

When body iron stores and erythropoiesis are adequate, iron export from enterocytes into the circulation is reduced by hepcidin-mediated internalization and degradation of Fe–ferroportin complex. The iron thus released from ferroportin is stored in ferritin. Under such conditions, the hepatic iron uptake is also reduced by downregulating the expression of the transferrin receptor through degradation of the transferrin receptor mRNA. In the enterocytes, the stored iron in ferritin is lost after 3 days by desquamation of intestinal cells (Anderson et al., 2012). Iron regulation of gene expression requires the presence of a 30-nucleotide long iron response element (IRE) in the 5′-untranslated or 3′-untranslated region of the target mRNAs. The IRE forms a special stem-loop structure. The IRE binds the iron regulatory protein (IRP), also called IRE-binding protein (IRE-BP). The IRPs are cellular iron sensors. The mRNAs associated with iron transport, distribution, and storage all contain IREs, such as DMT1, ferroportin, transferrin, and ferritin mRNAs. Some other mRNAs containing IREs include that of mitochondrial aconitase and succinate dehydrogenase. Fig. 27-5 shows how the binding of the IRP–Fe complex to IRE affects mRNA stability based on the location of the IRE in the 5′-UTR versus the 3′-UTR of the target mRNA. Other dietary minerals, such as zinc (Zn) and copper (Cu), regulate gene expression by activating metal regulatory transcription factor 1 (MTF1).

Dietary Polyphenols, Indoles, Carotenoids, and Gene Expression

Dietary polyphenolic constituents present in fruits, vegetables, and spices can mediate nutrient–gene interactions by activating or inhibiting specific transcription factor pathways (Ashida et al., 2008). These include both flavonoid polyphenols (e.g., quercetin, kaempferol, apigenin, tangeretin), and non-flavonoid polyphenols (e.g., resveratrol, curcumin). Indole-3-carbinol (I3C), present in cruciferous vegetables, and dietary carotenoids (e.g., canthaxanthin, astaxanthin) also mediate nutrient–gene interactions. I3C is derived from glucobrassicin (glucosinolate) (Fig. 27-11). These dietary constituents regulate gene expression through modulation of the aryl hydrocarbon receptor (AhR) pathway. Although AhR is known for its role in effecting the toxicity of dioxins and other environmental pollutants, it also plays important roles in normal biological processes, such as regulating anti-inflammatory response, and the development of the immune system.

Table 27-4 shows some transcription factor pathways involved in nutrient–gene interactions.

FOOD–DRUG INTERACTIONS

The food and drug interactions are in most part the results of food-induced changes in drug bioavailability or metabolism, although some are the result of altered drug concentrations at the site of action and the resulting effect. In other words, food–drug interactions can alter pharmacokinetic and pharmacodynamic parameters of the drug. For drugs with a narrow therapeutic index and the need for dose titration, even small changes in the dose–response effects can have great consequences (Schmidt and Dalhoff, 2002).

Examples of dietary constituents that may produce an effect on the overall pharmacokinetics of drugs would include food or food components that change the pH of urine or simply the presence of fiber in the intestine. Examples of pharmacodynamic interactions might include the effect of unsaturated fatty acids in the diet on anticoagulants or membrane potentials of the membranes in which they become incorporated, or high potassium intake from potassium-rich foods and the risk of hyperkalemia during therapy with angiotensin-converting enzyme inhibitors or spironolactone (Schmidt and Dalhoff, 2002). Some food–drug interactions, such as the effects of dietary constituents on the induction or inhibition of CYP3A4, may be potentially important because CYP3A4 metabolizes more than

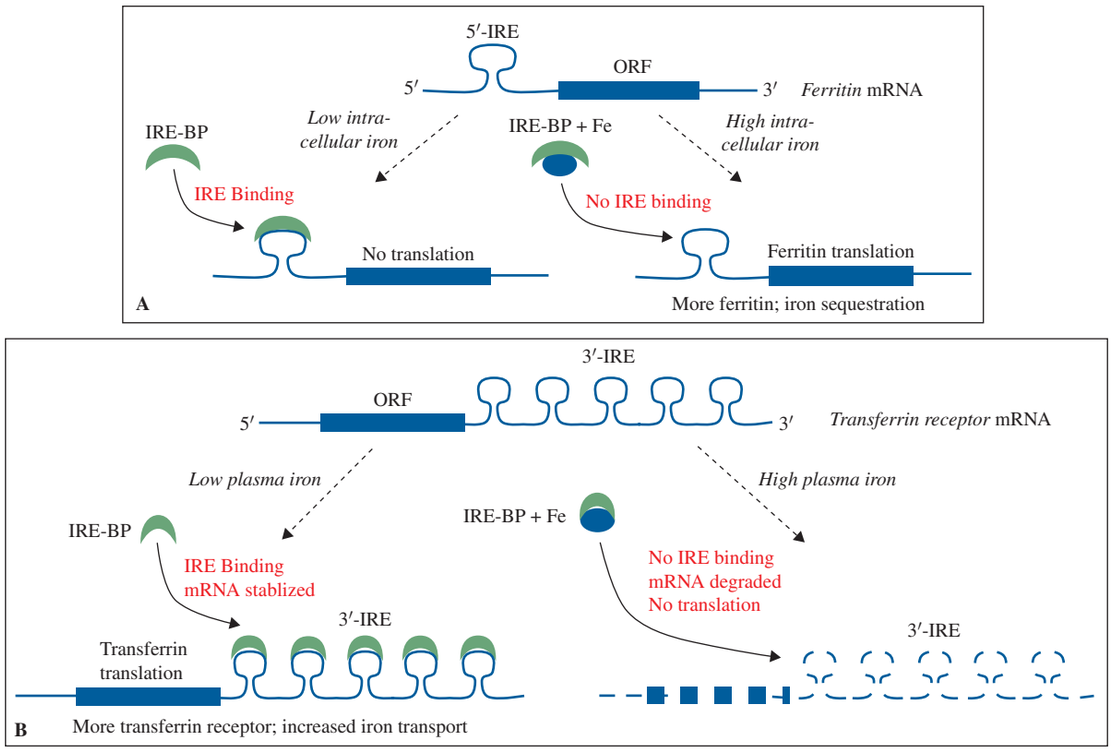

Figure 27-5. *When intracellular iron levels are high, IRP binds iron (Fe) and the IRP–Fe complex cannot bind to IRE in the 5′-UTR of ferritin mRNA.* **(A)** This allows ferritin mRNA to be translated to ferritin, which then sequesters excess intracellular iron. When intracellular iron levels are low, the IRP does not bind iron; hence it can bind to the IRE. As a result, the translation of the ferritin mRNA is prevented. When iron levels are low, transferrin receptor mRNAs are stabilized by the binding of IRP with the IREs in its 3′-UTR so that more transferrin receptors can be translated and cells can take up more iron from transferring. **(B)** Unlike ferritin mRNA which has a single IRE in 5′-UTR, transferrin receptor mRNA has multiple IREs in 3′-UTR. When iron levels are high, IRP binds iron and cannot interact with IREs; as a result, transferrin receptor mRNA is degraded at a faster rate to prevent over-uptake (thus, over-accumulation) of iron in the cell.

Table 27-4

Some Dietary Constituents That Mediate Nutrient–Gene Interactions by Modulating Specific Transcription Factor Pathways (Partial List)

FOOD/FOOD INGREDIENTS (SOURCE)	ACTIVATING CONSTITUENTS	TARGET TRANSCRIPTION FACTORS
Proteins	Amino acids	C/EBP, CHOP, IGFBP-1
Carbohydrates	Glucose	SREBPs, ChREBP, LXR
Fats	Fatty acids	SREBPs, ChREBP, PPARs, HNF-4, NF-κB, LXR, RXR
	Cholesterol	SREBPs, LXR, FXR, RXR
Vitamins	A	RAR, RXR
	D	VDR, RXR
Minerals	Fe	IRPs (IREBPs)
	Zn, Cu	MTF1
Vegetables and fruits	Flavonoid polyphenols (e.g., quercetin, kaempferol, apigenin, tangeretin)	AhR, Nrf2
Spices and wine	Non-flavonoid polyphenols (e.g., curcumin in turmeric, resveratrol in grapes and wine)	
Cruciferous vegetables	Indole-3-carbinol	
Salmon, shrimp	Carotenoids (e.g., canthaxanthin, astaxanthin)	

Table 27-5

Food–Drug Interactions (Activity May be Enhanced or Inhibited)

ENZYME OR TRANSPORTER	FOOD	DRUG
CYP1A2	Caffeine, theophylline, grapefruit juice (naringen and furanocoumarins bergamottin and dihydroxybergamotin), grape juice, cruciferous vegetables, apiaceous vegetables, cooked meat	Clozapine, fluvoxamine, imipramine
CYP2E1	Watercress and possibly other isothiocyanate-containing cruciferous vegetables; polyunsaturated fatty acids (corn oil, menhaden oil)	Ethanol, halothane, enflurane
CYP3A4	Grapefruit juice, orange juice, red wine, possibly other polyphenol-containing substances, St Johns wort, garlic	Ketoconazole, cyclosporin, erythromycin, protease inhibitors, 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors
UGT and GST	Brussel sprouts, cabbage, watercress, broccoli	Acetaminophen, oxazepam, morphine, ibuprofen
P-glycoprotein and OATP	Vegetables, fruit juice, St Johns wort	Digoxin, cyclosporine, pravastatin

Abbreviations: GST, glutathione-S-transferases; OATP, organic anion–transporting polypeptides; UGT, uridine diphosphate glucuronosyltransferases.

50% of all drugs consumed by humans. Thus, induction of CYP3A4 might enhance the clearance and reduce the efficacy of a drug. In contrast, inhibition of CYP3A4 might prevent the drug's metabolism, resulting in a gradual build-up of its serum concentration and causing toxicity (Choudhuri and Valerio, 2005; Kirby and Unadkat, 2007). Examples of foods affecting a number of phase I and phase II enzymes, and transporters are provided in Table 27-5.

FOOD SAFETY REGULATIONS IN THE UNITED STATES

The U.S. Food and Drug Administration

The United States (U.S.) Food and Drug Administration (FDA) has a wide responsibility for protecting public health that includes ensuring the safety of the nation's food supply. FDA began as the Division of Chemistry under the U.S. Department of Agriculture (USDA). The name changed to the Bureau of Chemistry in 1901. In 1927, the Bureau of Chemistry was reorganized into two separate entities; the regulatory functions became the responsibility of Food, Drug, and Insecticide Administration, and nonregulatory research became the responsibility of the Bureau of Chemistry and Soils. In 1930 the name was changed again to the Food and Drug Administration (Swan, 1998; http://www.fda.gov/AboutFDA/WhatWeDo/History/Milestones/ucm128305.htm). Within FDA, the Center for Food Safety and Applied Nutrition (CFSAN) is the center that is responsible for protecting the food supply. CFSAN's food safety mission involves all of the areas noted below:

- The safety of substances added to food, e.g., food additives (including sources of radiation) and color additives
- The safety of foods and ingredients developed through biotechnology
- Seafood and juice Hazard Analysis and Critical Control Point (HACCP) regulations
- Regulatory and research programs to address health risks associated with foodborne, chemical, and biological contaminants
- Regulations and activities dealing with the proper labeling of foods (e.g., ingredients, nutrition health claims)
- Regulations and policy governing the safety of dietary supplements, infant formulas, and medical foods
- Food industry postmarket surveillance and compliance
- Industry outreach and consumer education
- Cooperative programs with state, local, and tribal governments
- International food standard and safety harmonization efforts

Chemical risk assessment is a critical aspect of food toxicology; the chemicals of interest are natural toxicants found in food, substances intentionally added to food, substances that unintentionally become part of food, and contaminants. Microbial risk assessment, also critically important to food safety, will not be discussed here.

Historical Perspective on the Science of Food Toxicology

Food toxicology involves the study of the toxic substances in food and any adverse impact in humans that results from their ingestion. Early on in history, humans recognized that many plants including plants used for food contained poisonous substances. Such plants were either avoided or prepared in ways that mitigated concerns for toxicity. However, the history of food toxicology as it relates to substances intentionally added to food or becoming part of food via food processing or contamination began in the last decades of the 19th century.

In 1883, Dr Harvey Washington Wiley of Purdue University was named the Chief Chemist of the USDA. That era saw the beginning of numerous debates about the use of substances added to food, including chemical preservatives, such as benzoates and salicylates; flour-bleaching agents, such as nitrites and nitrogen peroxide; artificial sweeteners, such as saccharin; and food colors, such as synthetic coal-tar dyes. The issues raised in those debates formed the basis for the development of food toxicology during the early part of the 20th century. Dr Wiley recruited healthy male volunteers, the so-called "poison squad," whose job was to ingest various foods containing chemical additives under controlled conditions to test their purported health effects. The volunteers were fed many chemicals including borax; salicylic, sulfurous, and benzoic acids; and formaldehyde. The experiments went on for 5 years. Wiley and the public became convinced that chemical preservatives

should be used in food only when necessary. Wiley intended for his experiments to lead to the regulation of food additives but he was opposed by the food lobby. Nevertheless, the Pure Food and Drug Act was enacted by Congress in 1906 as the first federal law to regulate food; the poison squad was disbanded one year later (Janssen, 1981; Swan, 1998; Watson, 2013; http://www.fda.gov/AboutFDA/WhatWeDo/History/Milestones/ucm128305.htm). Relatively speaking, food toxicology as a scientific discipline did not significantly advance for another 30 years.

The 50 years between 1930 and 1980 witnessed considerable development of toxicology (Guengerich, 2004). After World War II, there was a significant growth in both the food and the chemical industry, which led to the development of chemicals such as pesticides. The beginning of toxicology as "the science of poisons" implied that death was an important endpoint measured in toxicology studies. In order to find out the adverse effects of a chemical, toxicologists of the time relied mainly on acute toxicity studies with a LD_{50} value as the endpoint. The concepts of longer-term studies with repeat dosing, the importance of various biochemical endpoints, species differences, and other factors determining toxicity were not appreciated until later.

During the post–World War II period, the concept of longer term, repeat dose, toxicity studies, and their utility took root in experimental toxicology. Using various short- and long-term toxicity studies with apical endpoints, food toxicology at FDA advanced within the Division of Pharmacology under the leadership of Dr O. Garth Fitzhugh. During the 1950s further advances were made under the new director of the Division of Pharmacology, Dr Arnold J. Lehman. FDA established an organized approach to evaluating the safety of chemical constituents of foods, drugs, and cosmetics in making safety decisions. In 1959, FDA published the document *Appraisal of the Safety of Chemicals in Foods, Drugs and Cosmetics* (Hattan and Rulis, 1999). In 1982, the FDA Center for Food Safety and Applied Nutrition (CFSAN), then known as the Bureau of Foods, published a document titled *Toxicological Principles for the Safety Assessment of Food Additives and Color Additives Used in Food,* often referred to as the "FDA Redbook." The safety standard applicable to food ingredients is *reasonable certainty of no harm under the conditions of intended use*. The Redbook has been updated several times since then, and FDA has published numerous additional guidance related to diverse aspects of food safety assessment. A web search using the search term "FDA Redbook" returns many relevant FDA links including a link to download the Redbook.

History of Food Law

The current federal law governing food safety is the result of incremental legislative actions over a period spanning more than 100 years. It began with the passage of the Pure Food and Drug Act of 1906 by the U.S. Congress, which prohibited interstate commerce in misbranded and adulterated foods, drinks, and drugs. The law declared a food to be adulterated if it contained "any added poisonous or other added deleterious ingredient which may render such article injurious to health" (Hattan and Rulis, 1999). This spurred efforts to investigate the potential adverse effects of inappropriate food chemicals. Although several publications reported various toxicological investigations during the first decade of the 20th century (when the law was passed), the science of toxicology was in its infancy. Therefore, the evaluation of food chemical safety using the toxicology testing paradigms currently practiced did not evolve until much later as described above. *It is interesting to note that the two concepts, "adulterated" and "misbranded," that were part of the 1906 Act, still provide the legal basis for food safety regulations*.

In 1933, FDA recommended a complete revision of the obsolete 1906 Pure Food and Drug Act. The first bill was introduced in the Senate, launching a five-year legislative battle. In 1937, the Elixir of Sulfanilamide containing the poisonous solvent diethylene glycol killed 107 individuals. This unfortunate event accelerated the passage of the 1938 Food, Drug, and Cosmetic Act (Janssen, 1981; Swan, 1998; http://www.fda.gov/AboutFDA/WhatWeDo/History/Milestones/ucm128305.htm). The Food, Drug, and Cosmetic Act (FD&C Act) of 1938 clarified the regulation of poisonous and deleterious substances in foods. Foods under this statute are considered adulterated if they contain added poisonous or deleterious substances that "may render the food injurious to health." In case a substance is not added but is naturally present, the food would be adulterated only if the substance present "ordinarily renders" the food injurious. The FD&C Act of 1938 introduced the concept of premarket approval. However, premarket approval by FDA at the time was required only for drugs, not food ingredients.

The 1938 FD&C Act provided FDA with the regulatory authority to stop the use of known poisons. However, the vast effort needed to assure that all food chemicals were safe was clearly beyond the available resources and regulatory authority. In 1949, FDA Commissioner Paul B. Dunbar presented the problem to Rep. Frank B. Keefe of Wisconsin. Mr Keefe introduced a resolution to investigate chemicals in food, and later, cosmetics. The hearings, chaired by Rep. James T. Delaney of New York, went on for 2 years. From the committee's work came three amendments that fundamentally changed the character of the U.S. food and drug law: the Pesticide Amendment (1954), the Food Additives Amendment (1958), and the Color Additive Amendments (1960) (Janssen, 1981).

The FDA Modernization Act (FDAMA) of 1997 further amended the 1958 FD&C Act to enhance FDA's mission. The FDAMA focused largely on reforming certain aspects of the regulation of medical products and cosmetics, and to a lesser extent it addressed the regulation of food additives by streamlining the review process for the food contact substances (FCSs). The FCSs are defined in Section 409 of the Act as "any substance intended for use as a component of materials used in manufacturing, packing, packaging, transporting, or to hold food if such use is not intended to have any technical effect in such food" [sec. 409(h)(6) of the Act] (FDA, 1997).

Current U.S. Food Law to Ensure Safety of Foods, Food Ingredients, and Food Contaminants

The FD&C Act along with its amendments provides the necessary regulatory tools to ensure the safety of food and food ingredients. The recent amendments include The Food Additives Amendment of 1958, the Color Additive Amendments of 1960, and FDAMA of 1997. The following discussion briefly focuses on the regulatory definitions and safety evaluation processes of food additives, generally recognized as safe (GRAS) ingredients, and color additives.

FD&C Act, FDA Regulations, and FDA Guidance

The United States Code (U.S.C.) is a compilation of all codified federal laws enacted by Congress. Each "Title" in the U.S.C. represents the subject matter for which federal laws have been enacted. Title 21 of the U.S.C. pertains to Food and Drug laws. Therefore, the FD&C Act (referred to as "the Act" below) is a federal law enacted by Congress and contained in Title 21 of the United States Code (21 U.S.C.). The Act provides the legal framework within which FDA

operates. The Act along with all its provisions can be accessed at http://uscode.house.gov/browse/&edition=prelim.

Once the Congress enacts a federal law, executive departments and agencies can publish further regulations based on the legal framework set forth in the federal law. FDA develops regulations based on the laws set forth in the Act and other laws under which FDA operates. An example of "other laws" is the Administrative Procedure Act. FDA follows the procedures required by the Administrative Procedure Act (5 U.S.C.) to issue FDA regulations. This typically involves a process known as "notice and comment rulemaking" that allows for public input on a proposed regulation before FDA issues a final rule. The rulemaking procedures also come from Executive Orders and memoranda issued by the President, and FDA's own regulations. The rules are first published in the *Federal Register*, the federal government's official publication. Rules are then codified into regulations (laws) in the code of federal regulations (CFR). *Therefore, FDA regulations are also federal laws, but they are not part of the FD&C Act*. FDA regulations can be found in Title 21 of the Code of Federal Regulations (21 CFR).

In contrast to FDA regulations that are federal laws, FDA guidance describes the agency's current thinking on a regulatory issue, and is not legally binding on the public or FDA. FDA follows the procedures required by its "Good Guidance Practice" regulation to issue FDA guidance. The Good Guidance Practice regulation can be found in 21 CFR 10.115 (http://www.fda.gov/AboutFDA/Transparency/Basics/ucm194909.htm).

Food Additives

Sections 201(s) of the 1958 Food Additives Amendment defines the term "food additive" very broadly. Food additive is defined as follows:

… any substance the intended use of which results or may reasonably be expected to result, directly or indirectly, in its becoming a component or otherwise affecting the characteristics of any food (including any substance intended for use in producing, manufacturing, packing, processing, preparing, treating, packaging, transporting, or holding food; and including any source of radiation intended for any such use), if such substance is not generally recognized, among experts qualified by scientific training and experience to evaluate its safety, as having been adequately shown through scientific procedures (or, in the case of a substance used in food prior to January 1, 1958, through either scientific procedures or experience based on common use in food) to be safe under the conditions of its intended use …

The 1958 Food Additives Amendment covers both "direct additives" and "indirect additives." Direct additives are described in 21 CFR Part 172 as substances added deliberately to food for a specific technical purpose; such substances usually remain in food as consumed. The technical effects could be intended to maintain or improve safety and freshness; improve or maintain nutritional value; or, improve taste, texture, and appearance. Secondary direct additives are described in 21 CFR Part 173 as substances added to food or food components during the manufacture or processing, but which are usually removed from the food before the product is consumed. Small amounts of these substances may remain in the final food. Examples of secondary direct additives include processing agents such as solvents, sanitizers, and defoaming agents. Indirect additives are described in 21 CFR Part 174 as substances that may become components of food, such as materials that may migrate from food contact surfaces during production, manufacturing, packing, processing, preparing, treating, packaging, transporting, or holding food. For premarket approval by FDA, a food additive must be demonstrated to be safe at levels of requested use (the Act, Section 409(c)(3)(A)). The actual addition of a substance to food should be at levels no higher than necessary to fulfill the desired technical effect, even if the safety data support a higher level of exposure (21 CFR 171.l(c)(C)).

Both indirect and some secondary direct additives are now referred to as food contact substances (FCSs). Therefore, FCSs are legally food additives. Some FCSs may still be evaluated by FDA under the premarket paradigm depending on the complexity and exposure. In 1958 the FD&C Act was amended by adding Section 409, which requires FDA to approve new food additives before they can be used in foods. Section 409-mandated premarket approval also applies to the FCSs. Section 309 of the FDAMA amended Section 409 of the Act (21 U.S.C. 348) to establish a food contact notification (FCN) process as the primary method by which FDA regulates food additives that are FCSs. In doing so, the FDAMA eliminated the food additive petition process for most packaging and other substances that come in contact with food and migrate into food, and established a notification program whereby a notifier notifies FDA about its intended use of the FCS(s). The notifier may use the FCSs unless FDA objects to the intended use. By law, FDA must respond within 120 days. The amendment did not alter the safety standard applied to all food additives. Therefore, the notification for an FCS must contain sufficient scientific information demonstrating that the substance is safe for the intended use. On January 18, 2000, the Agency began accepting new food contact notifications, and in July 2000 FDA published proposed regulations for the program. The regulations were finalized in May 2002 and codified in 21 CFR Part 170.100-106 (Shanklin and Sanchez, 2005). Table 27-6 shows some direct food additives based on functionality.

Table 27-6

Some Direct Food Additives by Functionality

NUMBER	DESIGNATION	DESCRIPTION	EXAMPLES
170.3(o) (1)	Anticaking agents and free-flow agents	Substances added to finely powdered or crystalline food products to prevent caking, lumping, or agglomeration	Glucitol, sodium ferrocyanide, silicon dioxide
(3)	Antioxidants	Substances used to preserve food by retarding deterioration, rancidity, or discoloration due to oxidation	Butylated hydroxyanisole, butylated hydroxytoluene, propyl gallate
(9)	Enzymes	Enzymes used to improve food processing and the quality of the finished food	Papain, rennet, pepsin
(12)	Flavor agents and adjuvants	Substances added to impart or help impart a taste or aroma in food	Cinnamon, citral, *p*-cresol, thymol, Zingerone
(19)	Non-nutritive sweeteners	Substances having less than 2% of the caloric value of sucrose per equivalent unit of sweetening capacity	Aspartame, neotame, sucralose, saccharin

Substances Generally Recognized as Safe (GRAS) While developing the definition of a food additive, it became clear that there are many foods and food ingredients that have a long history of safe use, such as butter, egg, salt, milk, vinegar, sugar, and others. Thus, the concept of generally recognized as safe (GRAS) was born. Under the 1958 Food Additives Amendment to the Act, any substance intentionally added to food is a food additive and is subject to premarket approval by FDA unless the use of the substance is generally recognized as safe (GRAS; the GRAS provision) or otherwise exempted from the definition of food additive (e.g., color additive). By 1961, FDA had amended its regulations to include a list of food substances that are GRAS under certain conditions of use ("the GRAS list") (Gaynor et al., 2006). The GRAS status of an ingredient can be based on either a safe history of "common use in food prior to 1958" (history of use) or "scientific procedures" that demonstrate safety.

The GRAS provision removed the requirement of premarket review by FDA, and provided for independent conclusions of GRAS status. In 1969, FDA removed cyclamate salts from its GRAS list as a result of safety questions, and then-President Nixon directed FDA to reexamine the safety of GRAS substances. In the 1970s, FDA began a "comprehensive review" of presumed GRAS substances and established rulemaking procedures to affirm the GRAS status of substances that were either on the GRAS list or the subject of a GRAS affirmation petition. If FDA concluded that the available data and information supported GRAS status, FDA issued a final rule affirming GRAS status by amending 21 CFR 184 (direct food ingredients) or 186 (indirect food substances). By affirming the GRAS status through rulemaking, FDA owned the GRAS conclusions. However, meeting this self-imposed regulatory burden became resource-intensive and was difficult to meet. To eliminate the resource-intensive rulemaking procedures, FDA proposed to replace the GRAS affirmation petition process with a notification procedure ("GRAS notification") (Gaynor et al., 2006).

On April 17, 1997 FDA proposed to move away from the GRAS affirmation petition process and establish the GRAS notification process, whereby a notifier could voluntarily inform FDA of its determination that the use of a substance is GRAS under the intended conditions of use (62 FR 18938; April 17, 1997). By law, premarket approval by FDA is not required for GRAS. The initial GRAS notification process was established under an interim policy and pilot program. It operated from 1997 until mid-August, 2016. By that time FDA had already reviewed more than 600 GRAS notices. On August 17, 2016 FDA published the final rule to amend and clarify the criteria for when the use of a substance in human food or animal feed is not subject to the premarket approval requirements of the Act because the substance is GRAS under the conditions of its intended use (81 FR 54959; August 17, 2016). The final rule became effective on October 17, 2016.

The GRAS notification process is voluntary like the GRAS affirmation petition process. However, from the regulatory perspective, the main differences are that the affirmation petition process was a premarket approval process and the onus of GRAS affirmation was on FDA, whereas the notification process is not premarket approval and the onus of GRAS determination is on the notifier. Because the onus of GRAS determination was on FDA in the GRAS affirmation petition process, it involved rulemaking (discussed above).

Color Additives

Section 201(t) of the 1960 Color Additives Amendment defines the term "color additive" as follows:

A color additive is any material, not exempted under section 201 (t) of the Act, that is a dye, pigment, or extracted, isolated, or otherwise derived with or without intermediate or final change of identity, from vegetable, animal, mineral, or other source and that, when added or applied to a food, drug, or cosmetic or to the human body or any part thereof, is capable (alone or through reaction with another substance) of imparting a color thereto. Substances capable of imparting a color to a container for foods, drugs, or cosmetics are not "color additives" unless the customary or reasonably foreseeable handling or use of the container may reasonably be expected to result in the transmittal of the color to the contents of the package or any part thereof. Food ingredients such as cherries, green or red peppers, chocolate, and orange juice which contribute their own natural color when mixed with other foods are not regarded as color additives; but where a food substance such as beet juice is deliberately used as a color, as in pink lemonade, it is a color additive.

Color additives are defined in 21 CFR, Section §70.3. Section §70.5 describes general restrictions on the use of color additives, such as use in the area of the eye, injections, and surgical sutures. The use of an unlisted color additive, the improper use of a listed color additive, or the use of a color additive that does not conform to the purity and identity specifications of the listing regulation may cause a product to be adulterated and could be subject to enforcement action by FDA. Under the Color Additive Amendments, approximately 200 color additives that were in commercial use at the time were provisionally listed and could be used on an interim basis until they were either permanently listed or terminated due to safety concerns or lack of commercial interest. After 1960, FDA gradually removed color additives from the provisional list either by permanent listing or by termination of listing. Today about half of the 1960 color additives remain listed (Barrows et al., 2003). Table 27-7 shows per capita intakes of certified color additives for the U.S. population.

Table 27-7

Per Capita Intakes of Certified Color Additives for the U.S. Population

COLOR ADDITIVE	U.S. POPULATION PER CAPITA EDI (mg/PERSON/DAY)	U.S. POPULATION PER CAPITA ADI (mg/person/day) (60-kg PERSON)	CHILDREN PER CAPITA ADI (mg/person/day) (30-kg CHILD)
FD&C Blue No. 1	1.72	720	360
FD&C Blue No. 2	1.95	150	75
FD&C Green No. 3	0.038	150	75
FD&C Red No. 3	0.61	150	75
FD&C Red No. 40	17.91	420	210
FD&C Yellow No. 5	12.06	300	150
FD&C Yellow No. 6	10.74	225	113

The Delaney Clause and Its Applications The Delaney clause [Section 409(c)(3)(A) of the Act] is a provision in the Food Additives Amendment of 1958. It states that no cancer-causing substance, as demonstrated in humans or animals, may be added to food. The 1960 Color Additive Amendments also contained the Delaney clause [Section 706(b)(5)(B) of the Act] that prohibited the use of a color additive shown to be a carcinogen in animal feed or human food.

A perusal of the scientific literature reveals that there is disagreement among experts regarding the utility of the blanket application of the Delaney clause with its zero-risk standard. Many scientists are of the opinion that it was needed at a time when the biology of carcinogenesis was poorly understood and the limits of detection of various residues in food were not nearly as sensitive as today's techniques, which have advanced from detection at the level of parts per thousand to parts per trillion or beyond. Advances in science ultimately triggered careful consideration of the zero-risk standard for carcinogens and action from the Congress through the passage of The Food Quality Protection Act (FQPA) of 1996 (21 U.S.C, §346A). The new law amended the zero-risk standard of the Delaney clause as it applies to pesticide residues in food, which are regulated by the U.S. Environmental Protection Agency (EPA). The new standard was based on quantitative risk assessment and determination of the lifetime risk of developing cancer from exposure to the pesticide residues in food. In practice, EPA targets a risk level of less than one in one million people (10^{-6}) over the course of a typical human life-span.

Except for the situation of pesticide residues in food discussed above, the Delaney clause still applies to food safety in general. The most conservative assumptions for the carcinogenic risk assessment result in an overestimation of the risk at each step ultimately leading to a combined overestimate of perhaps a million-fold or more. Therefore, an upper bound lifetime risk of one cancer or less in a million individuals is considered to be the biological equivalent of zero. Historically, FDA has employed a high threshold for establishing that a food or color additive has been found to induce cancer when ingested by humans or animals. Two indirect food additives (Flectol H and mercaptoimidazoline) that migrate from packaging material were banned. Among direct additives, safrole, cinnamyl anthranilate, thiourea, and diethylpyrocarbonate were banned because of the Delaney clause, and diethylpyrocarbonate because it forms urethane (Kotsonis and Burdoch, 2013).

Nevertheless, a number of substances (e.g., butylated hydroxyanisole [BHA], xylitol, methylene chloride, sorbitol, trichloroethylene, nitrilotriacetic acid [NTA], diethylhexyl phthalate, melamine, formaldehyde, bentonite) are listed in the CFR as food additives, but they are also listed as carcinogens by NTP, the International Agency for Research on Cancer (IARC), or the state of California (under the Safe Drinking Water and Toxic Enforcement Act of 1986, also known as Proposition 65). The reasoning applied by FDA in almost every case is based on secondary carcinogenesis, such as irritation and restorative hyperplasia in the forestomach in the case of BHA, mineral imbalance in the case of sugar alcohol, etc. The one exception is formaldehyde, which is carcinogenic only on inhalation, and inhalation is not an appropriate route for food additives (Kotsonis and Burdoch, 2013).

In an effort to restrict the applicability of the Delaney clause, FDA has narrowed the definition of food additive to exempt constituents and contaminants that pose a de minimis risk. According to FDA's constituents' policy, food additive refers to the added substance as a whole and not to each of its individual constituents. For example, the constituents' policy was employed to approve the use of FD&C Green No. 5 and Green No. 6, both of which contain a nonfunctional contaminant *p*-toluidine that by itself causes cancer (Picut and Parker, 1992).

For new animal drugs, safety assessment is concerned primarily with residues that occur in animal food products (milk, cheese, etc.) and edible tissues (muscle, liver, etc.). Toxicity studies require data on metabolism and the nature of metabolites, along with data on the drug's pharmacokinetics. During this phase, the parent drug and its metabolites are evaluated both qualitatively and quantitatively in the animal products of concern (eggs, milk, meat, etc.).

To comply with the no residue provision of the Delaney clause, FDA addressed the issue of residues of metabolites of animal drugs known to induce cancer in humans or animals. Because not every metabolite could be accurately tested, FDA considered threshold assessment. Threshold assessment combines information on the structure and in vitro biological activity of a metabolite for the purpose of determining whether carcinogenicity testing is necessary. If testing is necessary and if the substance is found to induce cancer, the FDA's definition states that a lifetime risk of one in a million is equivalent to the meaning of "no residue" as intended by Congress (Kotsonis and Burdoch, 2013).

The Safety Standard and Toxicological Testing Recommendations for Food Ingredients The following narrative is a general discussion on the toxicological testing recommendations for food ingredients, such as food additives, color additives, GRAS ingredients, and FCSs. Section 409 of the 1958 Food Additives Amendment states that before a food additive can be added to food, it must be demonstrated to be safe under its intended conditions of use. This statute is the foundation of the premarket approval of food additives, including FCSs. Congress, however, realized that it is impossible to assure the absolute safety of food additives under all circumstances. Thus, Section 409 states, "Safety requires proof of *a reasonable certainty* that *no harm* will result from the intended use of an additive." In other words, Congress recognized that absolute certainty of no harm (zero risk) was impossible to achieve. Thus, the safety standard for food and color additives is *reasonable certainty of no harm*. The same safety standard also applies for the other food ingredients.

In 1982 the FDA published a document titled *Toxicological Principles for the Safety Assessment of Direct Food Additives and Color Additives Used in Food*. This is popularly known as "the Redbook." In the Redbook, FDA provided its recommendations for the minimum set of toxicological data normally needed for evaluating the safety of the use of direct food additives. The 1982 Redbook was updated in 1993 and 2000 (Revised October 2001, November 2003, April 2004, February 2006, and July 2007) (FDA Guidance for industry). The original Redbook of 1982 is referred to as Redbook I, the 1993 updated version is referred to as Redbook II or Redbook 1993, and the 2000 version is called Redbook 2000. The Redbook is available to the public on the world-wide-web.

The recommendations in the Redbook utilize the concept of structure–activity relationships of chemicals to assign categories to substances added to food. Additives with functional groups with a high order of toxicity are assigned to category C, those with low potential for toxicity are assigned to category A, while those of unknown or intermediate toxicity are assigned to category B. Further, based on structure assignment and calculated exposure, "concern levels" are assigned. Concern levels are relative measures of the degree to which the use of an additive may present a hazard to human health. Concern level III represents the highest probable risk to human health, Concern level I represents the lowest probable risk, and Concern level II is intermediate between high and low risk (Table 27-8). Each concern level is associated with a different level

Table 27-8

Assignment of Concern Levels Based on Structure Category and Exposure

STRUCTURE CATEGORY A	STRUCTURE CATEGORY B	STRUCTURE CATEGORY C	CONCERN LEVEL
<0.05 ppm (= <50 ppb) in the total diet	<0.025 ppm (= <25 ppb) in the total diet	<0.0125 ppm (= <12.5 ppb) in the total diet	**I**
or	or	or	
≥0.05 ppm (= ≥50 ppb) in the total diet	≥0.025 ppm (= ≥25 ppb) in the total diet	≥0.0125 ppm (= ≥12.5 ppb) in the total diet	**II**
or	or	or	
≥1 ppm in the total diet	≥0.5 ppm in the total diet	≥0.25 ppm in the total diet	**III**

of initial toxicological testing. Listed in Table 27-9 are the recommended initial testing batteries for substances assigned to Concern levels I, II, and III. These represent the minimum testing recommendations; more extensive testing may be needed to resolve scientific questions that may arise during research and development. While testing in human subjects is not required for the safety assessment of many food additives, certain circumstances or scientific issues arise that may profit from this type of testing. For example, comparison of data from metabolism and pharmacokinetic studies in human subjects and test animals may be used to identify the species that provides the most accurate reflection of a toxicological effect in human subjects. The FDA expects that any toxicological testing that is conducted to provide data to support the safety of food additives will comply with its regulations entitled *Good Laboratory Practice for Nonclinical Laboratory Studies* that are found in 21 CFR 21.58 (Hattan and Rulis, 1999).

FDA scientists review the data and information submitted by the sponsor in support of the safety of a new additive or a new use of an additive or GRAS ingredient and they independently determine whether the intended use is consistent with the safety standard of reasonable certainty of no harm. Once the FDA determines that the intended use of the food/color additive is safe, it issues a regulation permitting the addition of the new food additive to food. In the case of GRAS ingredients, it is the notifier that determines whether the ingredient is GRAS for its intended use in food. FDA reviews the data and information provided by the notifier and determines whether it has no questions to the notifier's conclusion that the ingredient is GRAS for its intended use, or whether it finds that there is no basis to conclude that the ingredient is GRAS for its intended use. Therefore, FDA does not have to write a regulation for GRAS ingredients because FDA does not "own" the safety conclusion.

In the revised guidance for industry for the FCSs, FDA provided the minimum safety testing recommendations that depend on the exposure to the FCS in the diet. For example, no safety studies are recommended for an FCS (or a constituent, as appropriate) if exposure for a single use is at or less than 0.5 ppb [see the section "Threshold of Regulation (TOR)"]. If the cumulative exposure is between 0.5 ppb and 50 ppb, the potential carcinogenicity of the FCS (and/or a constituent, if appropriate) should be evaluated using genetic toxicity tests, such as (1) a test for gene mutations in bacteria and (2) an in vitro test with cytogenetic evaluation of chromosomal damage using mammalian cells or an in vitro mouse lymphoma $tk^{\pm}$ (thymidine kinase) assay. If the cumulative exposure is between 50 ppb and 1 ppm the potential carcinogenicity of the FCS (and/or a constituent, if appropriate) should be evaluated using genetic toxicity tests, such as (1) a test for gene mutations in bacteria; (2) an in vitro test with cytogenetic evaluation of chromosomal damage using mammalian cells *or* an in vitro mouse lymphoma $tk^{\pm}$ assay (the mouse lymphoma assay is preferred); and (3) an in vivo test for chromosomal damage using rodent hematopoietic cells. If the estimated exposure to an FCS or a constituent is 1 ppm or greater, FDA recommends that a food additive petition be submitted for the FCS (FDA, 2002).

ADI, EDI, and Reasonable Certainty of No Harm The goal of the toxicological testing of a food additive is to determine the acceptable daily intake (ADI) of the additive. The ADI is compared to the estimated daily intake (EDI) of the additive to determine whether the proposed use of the additive falls within the bounds of "reasonable certainty of no harm." In order to calculate the ADI, FDA uses the longest duration study in the most appropriate animal species to establish the no-observed-adverse-effect-level (NOAEL). The NOAEL is the highest dose that does not cause any observed adverse effects. By applying an appropriate safety factor to this NOAEL, the ADI is obtained. The standard safety factor is usually 100, which is derived by multiplying a factor of 10 to account for interspecies variation with an additional factor of 10 to account for intraspecies variation in the sensitivity of response to a chemical. Hence, ADI = NOAEL /100.

The default safety factor of 100 may be modified (lowered or increased) based on various considerations, including the number of

long-term studies, number of species in which these studies are conducted, the nature of the toxicological effect found, the nature of the food additive, or the extent and the quality of supporting data. For micronutrients, for example, it may not be possible to apply a 100-fold safety factor to a NOAEL and have an adequate dietary intake to allow them to fulfill their physiological roles. In such instances, a 10-fold or lower safety factors are not uncommon. The same is true for *macroingredients*, which are food additives intended to replace macronutrients (e.g., fats) in the diet. Macroingredients are added to food in appreciable quantities in order to impart their technological purpose. An example is olestra, which is a fat substitute. Animals were fed up to about 6 g/kg body weight/day whereas the human 90th percentile intake of olestra for just one food category, snack foods, is 0.33 g/kg body weight/day (Hattan and Rulis, 1999). The traditional safety factors are not applied to substances that have been demonstrated to be carcinogenic in humans or animals. This is because Delaney clause prohibits the addition of carcinogenic food additives to the food supply.

Typically, if the EDI is less than the ADI (in the same units, such as mg/kg body weight/day), the use of the additive or a GRAS ingredient is considered to lie within the bounds of "reasonable certainty of no harm," for its intended use in food. GRAS ingredients are often macroingredients and it is not possible to feed enough to experimental animals in order to calculate an ADI based on 100-fold safety factor.

Dietary Intake Estimate The FDA's pre-market approval processes for food and color additives require an estimate of the *probable* consumer intake of the additive to determine whether its use or presence in a food at a given concentration is safe. The basis for this requirement is stated in the Act as amended in 1958 (Section 409—food additives) and 1960 (Section 721—color additives). In addition, FDA also considers consumer intake of contaminants that may be present in foods. Under Section 402(a)(1)-adulterated food, a food shall be deemed to be adulterated if it bears or contains any poisonous or deleterious substance which may render it injurious to health (FDA, 2006a). In 2006 FDA revised its 1995 guidance on estimating dietary intake of substances in food. The document uses the term "ingredient" to refer generically to substances intentionally added to food, including food additives, GRAS ingredients, color additives, and prior-sanctioned substances.

The dietary intake (dietary exposure) is an important contributor to the development of the concern level. Estimates of intake of an ingredient or chemical constituent of food require two key pieces of information: (1) the concentration of the substance in a food, and (2) consumer intake of foods that will or might contain the substance (FDA, 2006a).

The concentration of an ingredient in food can be obtained from (1) the intended use levels of the substance in target foods; (2) the measured concentration in food as consumed; (3) the limit of detection (LOD) or limit of quantification (LOQ) of the analytical method; (4) established limits for the substance (e.g., specifications in the CFR or the Food Chemical Codex [FCC] for unavoidable impurities and contaminants in food ingredients, or maximum allowable levels of impurities and contaminants in foods adopted by a recognized standards-setting body, such as the Codex Alimentarius Commission) (FDA, 2006a).

The consumer intake can be obtained from a number of sources that provide intake estimates of substances in the diet, such as (1) food consumption surveys; (2) food/ingredient disappearance data; (3) total diet study; (4) body burden/excretion measurements, or "biomarkers." *Food consumption data* may be collected at the national, household, or individual level. Examples of some frequently used food consumption surveys are Continuing Survey of Food Intakes by Individuals (CSFII), National Health and Nutrition Examination Survey (NHANES), and the integrated CSFII/NHANES, and MRCA 14-Day Survey. *Food/ingredient disappearance data* represent the disappearance of food into the marketing system. Annual amounts of major U.S. commodities entering into the U.S. food supply are determined by subtracting data on exports, year-end inventory, and non-food use from data on production, imports, and beginning inventories. In the United States, information on the poundage of many food commodities entering commerce is available annually from the Economic Research Service (ERS) of the USDA. An online database of poundage-based per capita food consumption is also available from the ERS, which permits customized searches of commodities (e.g., meat) and sub-commodities (e.g., red meat, poultry, fishery products) by year. *FDA's Total Diet Study* (TDS; also called the market basket study) is an ongoing program through which the Agency monitors and analyzes a wide range of foods to determine levels of selected substances (e.g., nutrients, pesticide residues, and industrial contaminants). The TDS has been conducted continuously in the United States since the early 1960s. The program currently uses four regional sample collections (or market baskets) each year. FDA updates the list of foods to be surveyed about every 10 years to reflect changes in food consumption patterns. *The use of biomarkers* for estimating intake has been investigated for methyl mercury, fumonisins, phthalate diesters, and several nutrients (e.g., fat, protein, minerals, and vitamins). The use of biomarkers in exposure assessment methods is the subject of ongoing research. For a detailed discussion of these topics as well as additional sources of information, see FDA (2006a).

The relationship of substance concentration data, portion size, and food consumption frequency to the estimated daily intake (EDI) of a substance X for a single individual is captured in the following equation (FDA, 2006a):

$$\mathrm{EDI}_x = \sum_{f=1}^{F} \frac{\mathrm{Freq}_f \times \mathrm{Port}_f \times \mathrm{Conc}_{xf}}{N}$$

where
F = Total number of foods in which substance "x" can be found
Freq_f = Number of eating occasions of food "f" over "N" survey days
Port_f = Average portion size for food "f"
Conc_{xf} = Concentration of the substance "x" in food "f"
N = Number of survey days

Threshold of Regulation (TOR) In 1995, the FDA introduced the threshold of regulation (TOR) policy and established procedures for exempting indirect food additives (now called FCSs) from premarket evaluation and petition review if the likely dietary exposure to humans from the migrating substances is below 0.5 ppb (21 CFR 170.39). The TOR policy is based upon the notion that below certain dietary exposure levels, additives migrating into food will present only negligible risk. The policy is intended only for substances not known or expected to be carcinogenic, but is based upon the presumption that even if a migrating substance were inadvertently a carcinogen, the upper-bound risk of cancer from exposure to the substance at the low levels permitted would be negligible. The policy is based upon a systematic analysis of the potencies of numerous carcinogens and noncarcinogens (Hattan and Rulis, 1999).

Food from New Plant Varieties FDA regulates the safety of food for humans and animals produced from new plant varieties, including genetically engineered (GE) plants. The safety of new

plant varieties is regulated primarily under the FDA's postmarket authority [section 402(a)(1) of the act (21 U.S.C. 342(a)(1)]. This section, normally applied to occurrences of unsafe levels of toxicants in food, is applied to new plant varieties whose composition has been altered by an added substance. Foods from GE plants must meet the same food safety requirements as foods derived from traditionally bred plants.

The FDA published its "Statement of Policy: Foods Derived from New Plant Varieties", the 1992 policy (FDA, 1992) in the Federal Register in 1992 (57 FR 22984–23005). In the 1992 policy, the FDA explained that under the Act developers of new foods have a responsibility to ensure that the foods they offer to consumers are safe and in compliance with all requirements of the Act. The 1992 policy applied to all foods (such as fruits, vegetables, grains, and their byproducts) derived from all new plant varieties, including varieties that are developed using recombinant DNA technology. The plant varieties that are developed using recombinant DNA technology are referred to as "bioengineered foods."

In the 1992 policy, the FDA provided guidance to the industry regarding scientific considerations for evaluating the safety and nutritional aspects of food from new plant varieties derived by traditional methods (such as hybridization or mutagenesis), tissue culture methods (such as somaclonal variation and protoplast fusion), and recombinant DNA methods. FDA recognized in its 1992 policy statement that it is prudent practice for developers of new varieties to consult with the agency on safety and regulatory questions, especially with regard to products developed through new technology. Because of the rapid advances in recombinant DNA technology (bioengineering), FDA believes that it is in the best interests of the regulated industry and the agency for developers to inform FDA prior to commercial distribution, about foods or feed derived from new plant varieties, including those derived using recombinant DNA technology. FDA issued guidance on the consultation process in 1996, which was revised in 1997 (FDA, 1997a).

In the United States, new plant varieties are regulated not only by FDA, but also by the EPA and USDA. FDA is responsible for the safety and labeling of foods and feeds derived from crops, irrespective of the method used to produce the new plant variety. The EPA is responsible for assuring the safety of pesticides; thus, if a pesticidal protein is produced in a new plant variety, this product would also fall under EPA's jurisdiction. The USDA's Animal and Plant Health Inspection Service (APHIS) has responsibility for the environmental safety of field testing and commercial planting of new plant varieties. The developer of a biotechnology-derived crop variety must obtain registration from not only the country of origin but from importing countries as well (Kotsonis and Burdoch, 2013).

The Food Allergen Labeling and Consumer Protection Act (FALCPA) In 2004, an amendment to the FD&C Act (Public Law 108-282) was introduced mandating the labeling of a food that contains an ingredient that is or contains protein from a "major food allergen." This is the Food Allergen Labeling and Consumer Protection Act (FALCPA), which became effective January 1, 2006. For a series of questions and answers on FALCPA, see FDA (2006b). According to FALCPA, manufacturers are required to identify the presence of ingredients that contain proteins derived from milk, eggs, fish, crustacean shellfish, tree nuts, peanuts, wheat, or soybeans, and also specify the source when possible. For example, specify the type of tree nut (e.g., almonds, pecans, or walnuts), the species of fish (e.g., bass, flounder, or cod), and the kind of crustacean shellfish (e.g., crab, lobster, or shrimp). Also, because the source of ingredients such as lecithin, flour, or whey may not be obvious to the consumer, the source must follow the name of the ingredient. For example, lecithin, flour, and whey must be given on the labels as follows: lecithin (soy), flour (wheat), and whey (milk); alternatively, immediately after or next to the list of ingredients in a "contains" statement—for example "Contains wheat, milk, and soy."

Food Safety Through the Hazard Analysis and Critical Control Point (HACCP) System The HACCP is a management system in which food safety is addressed through the analysis and control of biological, chemical, and physical hazards from raw material production, procurement, and handling, to manufacturing, distribution, and consumption of the finished product. The current practice of HACCP was developed over time, but the initial trigger came from the need to provide safe food for space flights (Sperber and Stier, 2009–2010). In the United States, the initial participants were the United States Army Laboratories, the National Aeronautics and Space Administration (NASA), and Pillsbury. Pillsbury and NASA required contractors to identify the critical control points (CCPs), that is, the "critical failure areas" and eliminate them from the system. In the 1970s, several cases of *Clostridium botulinum* contamination were attributed to under-processed, low-acid canned foods. FDA asked Pillsbury to organize a training program for its inspectors. This training program, "Food Safety through the Hazard Analysis and Critical Control Point System," was held in 1972, and appears to be the first published use of the term "HACCP" (Sperber and Stier, 2009–2010).

The National Advisory Committee on Microbiological Criteria for Foods (NACMCF) was established in 1988. It is an advisory committee chartered under the USDA and comprises participants from the USDA (Food Safety and Inspection Service), Department of Health and Human Services (FDA and CDC), the Department of Commerce (National Marine Fisheries Service), the Department of Defense (Office of the Army Surgeon General), academia, industry, and state employees. When the NACMCF was established, the HACCP system was already in place. However, one of the first NACMCF efforts was the definition of an HACCP system and guidelines for its application. Its efforts were coordinated with those of the Codex Committee for Food Hygiene (permanently chaired by the United States), leading to reports from each group in 1992, which were further harmonized in 1997. Since its birth in 1959 and formalization in 1972, the HACCP system has grown from three to seven principles (Sperber and Stier, 2009–2010). The seven principles of HACCP are: (1) Hazard analysis; (2) Identification of CCPs; (3) Establishing the critical limits; (4) Monitoring control of the CCPs; (5) Establishing corrective actions; (6) Establishing verification procedures; and (7) Establishing documentation and record-keeping systems. The HACCP principles and application guidelines adopted in 1997 can be accessed at the FDA website (FDA, 1997b). The links to dairy HACCP, juice HACCP, retail and food service HACCP, and seafood HACCP can all be accessed from there.

The Food Safety and Modernization Act (FSMA) The FDA Food Safety and Modernization Act (FSMA) was signed into law by the President on January 4, 2011. It aims to ensure the safety of the U.S. food supply by shifting the focus from responding to contamination to preventing it. In other words, FDA can use regulation to prevent food safety problems before they occur. The FSMA provides FDA with new enforcement authorities related to food safety standards, provides FDA tools to hold imported foods to the same standards as domestic foods, and directs FDA to build an integrated national food safety system in partnership with state and local authorities. One of the most important enforcement tools the FDA has under the FSMA is the power to withdraw a food facility's registration.

The major elements of FSMA include (1) Preventive controls; (2) Inspection and compliance; (3) Imported food safety; (4)

Response; and (5) Enhanced partnerships. The new food safety plan requires the identification and prevention of all reasonably foreseeable food safety hazards that could be natural or unintentionally introduced into the food facility. This goes beyond the practice of HACCP. This new process is called Hazard Analysis and Risk-Based Preventive Controls (HARPC), which is the plan and the process that a food company has to use in each of its facilities to implement its food safety plan. Simply stated, it is the system used to control the different hazards found in various facilities that manufacture food. Each food manufacturing facility owned and operated by a food company must have its own HARPC plan if there are any differences in the foods it manufactures between facilities (King and Ades, 2015). The facilities and the products that are already in compliance with HACCP are exempt from HARPC, such as the juice and seafood HACCP-compliant facilities, and HACCP-compliant facilities involved in packaging thermally processed low-acid foods in hermetically sealed containers. FDA provides a detailed FAQ on FSMA that explains various aspects of this law, including the background of its genesis, utility, and applications (FDA FSMA FAQ). While HACCP is a recognized global standard, HARPC is a U.S. standard set forth by FSMA, although there are similarities. In the FAQ (PC7), it is stated that the HACCP systems that many FDA-regulated manufacturers have in place are the foundation of the preventive controls regulations. Although there are similarities between the FSMA preventive controls requirements and the HACCP system, not every provision is identical. For example, in HACCP systems, controls are applied at CCPs, whereas preventive controls include controls at CCPs or controls other than those at CCPs that are appropriate for food safety (https://www.fda.gov/NewsEvents/PublicHealthFocus/ucm239907.htm; https://www.fda.gov/Food/GuidanceRegulation/FSMA/).

Regulation of the Dietary Supplements A dietary supplement is a product intended for ingestion that contains a dietary ingredient intended to add further nutritional value to (supplement) the diet. A dietary ingredient may be one, or any combination, of the following substances: a vitamin, a mineral, an herb or other botanical, an amino acid, a dietary substance for use by people to supplement the diet by increasing the total dietary intake, a concentrate, metabolite, constituent, or extract. Dietary supplements must be labeled as such and must not be represented for use as a conventional food or as the sole item of a meal or the diet. One way to distinguish dietary supplements from conventional foods is by looking at the nutrition information on the label of the product. Conventional foods must have a *Nutrition Facts* panel on their labels, but dietary supplements must have a *Supplement Facts* panel.

FDA regulates dietary supplements under a different set of regulations than those covering conventional foods. This regulation is called the Dietary Supplement Health and Education Act of 1994 (DSHEA). Under DSHEA, dietary supplement manufacturers and distributors are not required to obtain premarket approval from FDA before marketing dietary supplements, but they are responsible for evaluating the safety and labeling of their products before marketing to ensure that they meet all the requirements of DSHEA and FDA regulations. In other words, manufacturers and distributors are prohibited from marketing products that are adulterated or misbranded. FDA can take action against any adulterated or misbranded dietary supplement product after it reaches the market. In August 2016, FDA issued revised draft guidance for the industry regarding the New Dietary Ingredient (NDI) notification process that replaced the earlier guidance of 2011.

The information discussed above and additional information on various aspects of dietary supplements and their regulation can be obtained from the following link (and all the other links provided therein): https://www.fda.gov/Food/DietarySupplements/.

It should be noted that terms such as "functional foods" or "nutraceuticals" are widely used in the marketplace these days. But these terms are not defined by law, that is, these terms do not have any legal definition for regulatory use. Such foods are regulated by FDA under the authority of the FD&C Act.

Global Food Safety Authoritative Bodies

In parallel with U.S. FDA's effort to assure the safety of food additives, similar efforts were started internationally. The evaluation of food additives at the international level was initiated as a result of a Joint Food and Agriculture Organization (FAO)/World Health Organization (WHO) Conference on Food Additives held in Geneva, Switzerland in 1955. The Conference recommended to the Directors-General of FAO and WHO that expert committees should be convened to address the safety of chemical additives in food. The outcome of the recommendation was the establishment of an international expert scientific committee known as the Joint FAO/WHO Expert Committee on Food Additives (JECFA), which has been meeting since 1956. JECFA developed the concept and coined the term "acceptable daily intake (ADI)" in 1961 (Lu, 1988; http://www.fao.org/3/a-at863e.pdf).

Several other global food safety authoritative bodies were established since the 1990s, such as the Food Standards Australia and New Zealand (FSANZ), European Food Safety Authority (EFSA), and others. FSANZ was formally established in 2002 but its predecessor, called Australia New Zealand Food Authority (ANZFA), was established in 1996. FSANZ is a bi-national government agency that develops and administers the food standard code for Australia and New Zealand. The food standard code, which is publicly available on the web (http://www.foodstandards.gov.au/code/Pages/default.aspx), lists requirements for foods such as additives, food safety, labeling, and genetically engineered foods. The decisions made by FSANZ have to be approved by both governments (http://foodregulation.gov.au/internet/fr/publishing.nsf/Content/history-and-governance).

The European Food Safety Agency (EFSA) is another relatively recent global food safety authoritative body. The EFSA was legally established by the European Union (EU) under the General Food Law and is funded by the EU. It was set up in 2002 following a series of food crises in the late 1990s and it serves as a source of scientific advice and communication on risks associated with the food chain. The General Food Law created a European food safety system in which the responsibility for risk assessment (science) and for risk management (policy) are kept separate. EFSA is responsible for the risk assessment (science), and also has a duty to communicate its scientific findings to the public. As the risk assessor, EFSA produces scientific opinions and advice that form the basis for European policies and legislation, and it covers Food and feed safety; Nutrition; Animal health and welfare; Plant protection; and Plant health. EFSA's scientific opinions are mostly published in the *EFSA Journal* and are publicly available at https://www.efsa.europa.eu/en/aboutefsa.

TOXIC SUBSTANCES IN FOOD

The requirement for food varies with age and activity level. The average daily consumption of food is about 2 kg/day. Obviously, human beings consume a lot of materials as food on a daily basis. Thus, any hazard present in foods, such as toxic substances,[5]

[5]*Toxic substance* is a general term. Typically, toxic substances produced by living organisms are referred to as *toxins*, whereas toxic substances produced by human activities are referred to as *toxicants*.

antinutrients, or contaminants may have adverse health consequences. Discussed below are certain common toxic substances in food that are either naturally occurring, or formed during cooking, or they find their way into the food as contaminants during processing of foods. The list is by no means complete. The human and animal exposure to many of these toxins/toxicants has been significantly reduced because of our understanding of these toxins and their toxicity.

Some Naturally Occurring Toxic Substances in Food

Plants produce a stunning array of chemicals to protect themselves from invading pathogens, insects, and herbivorous animals. Many of these chemicals are secondary metabolites; they are not essential for growth and reproduction. Some of these secondary metabolites may have beneficial health effects on humans, usually at a low or moderate level of consumption. However, many others are toxic to animals and humans, particularly when consumed at high levels. The secondary metabolites usually belong to one of the three major chemical classes: *terpenoids* (contain isoprene units), *phenolics* (contain phenol group), and *alkaloids* (contain nitrogen). There are also nitrogen-containing non-alkaloids. Some of these toxic substances are fatty acids or proteins. Understanding how plant defense mechanisms work is essential to protecting our food supply as well as developing disease-resistant plant varieties. *In the following description, one representative chemical structure from each group of substances is shown.*

Cycasin Cycasin (an alkaloid; Fig. 27-6) is an azoxyglycoside found in cycads. Cycasin and its metabolite methylazoxymethanol (MAM) can be extracted from seeds and roots of cycad plants (Laqueur and Spatz, 1968). The inhabitants of Guam (Chamorros) have long used various parts of *Cycas circinalis*, including seeds, as a source of food before its toxicity was recognized. They also relished the meat of flying fox, a type of fruit bat that lived on cycad seeds. The consumption of cycad seeds was correlated with a complex neurodegenerative disease known as amyotrophic lateral sclerosis-parkinsonism-dementia (ALS-PDC) that occurred at a far higher rate compared to the rest of the world. Studies trying to identify the putative neurotoxin in Cycad seeds, roots, and leaves identified cycasin as a carcinogenic compound in rabbits, monkeys, and multiple species of rodents, although the neurotoxicity was not confirmed. In the animal studies cycasin induced tumors in multiple organs, such as the liver, kidney, lung, and intestine. Oral doses of cycasin induced tumors in conventional rats but not in germ-free rats, suggesting that intestinal metabolism of cycasin produced the carcinogen. Several reports confirmed that the β-D-glucosidase of intestinal bacteria hydrolyzes cycasin into its aglycone metabolite MAM, and that MAM was the toxicant and the ultimate carcinogen in rodents (Sieber et al., 1980). The incidence of ALS-PDC among Chamorros fell sharply after 1960 because of the awareness of cycad seed toxicity.

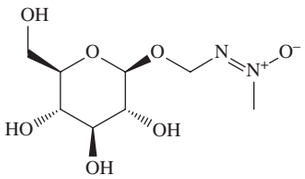

Figure 27-6. *Cycasin.*

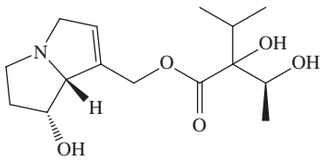

Figure 27-7. *Lycopsamine.*

Pyrrolizidine Alkaloids Pyrrolizidine alkaloids (PAs) are found in many species of flowering plants. Several hundred PAs have been isolated from these plants. PA structure has two parts: the bicyclic necine base (necine) that shares a bridgehead nitrogen atom and the necic acid, a C5-C10 branched chain acid that is esterified to necine. Some examples of PAs are *heliotrine*, *lycopsamine* (Fig. 27-7), *lasciocarpine*, *retrorsine*, and *senecionine*. Animals can be exposed to PA from the consumption of PA containing plant material, whereas human exposure results from the consumption of either the plant material or products of animal origin (Wiedenfeld, 2011). PAs are metabolized in the liver to electrophilic pyrrole derivatives, which cause hepatotoxicity in animals and veno-occlusive disease in humans. Many PAs also have genotoxic and carcinogenic properties (EFSA, 2011). In vitro studies and in vivo studies in big blue transgenic rats demonstrated that upon metabolic activation, PAs form DNA adducts and DNA strand breaks, leading to mutations and chromosomal aberrations. The major type of mutation was GC→TA transversions and tandem base substitutions of G:G to T:T and G:G to A:T, which is consistent with a mechanism involving adduct formation at guanine residues (G). The main carcinogenic target site for PAs in animals is the liver. There are no human epidemiological data on PA carcinogenesis (EFSA, 2011). However, it has been hypothesized that carcinogenesis may be favored by extended exposure to PAs. The U.S. Food and Drug Administration (FDA) issued an advisory in 2001 asking the dietary supplement manufacturers to remove the herb comfrey from their products because comfrey contains PAs.

Ptaquiloside Ptaquiloside (a terpenoid; Fig. 27-8) is a norsesquiterpene glucoside, and is the major carcinogen in bracken fern (*Pteridium aquilinum*). It causes bladder and intestinal cancer in livestock, mammary and intestinal tumors in rats, as well as neurotoxicity in mice and sheep. In addition to the ptaquiloside (PTA), bracken fern contains a number of other toxic substances, such as *prunasin* (a cyanogen glycoside) and *thiaminase*. The thiaminase splits thiamine (vitamin B1) into its two inactive components, pyrimidine and thiazole, causing thiamine deficiency. Bracken-fed cows secrete PTA in the milk and the concentration is dependent on the amount of bracken fern ingested by the cow. After the ingestion of the plant material or contaminated milk, both PTA and its aglycone ptaquilosin are converted by the hepatic CYP enzymes into the unstable dienone, which is a strong electrophile. This dienone

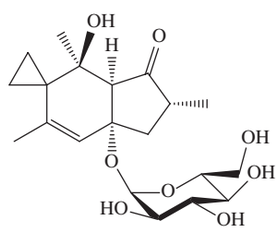

Figure 27-8. *Ptaquiloside.*

is the ultimate carcinogen; it rapidly reacts with DNA, forming covalent adducts and DNA strand breaks. The PTA in milk may be responsible for the incidence of gastric cancer in the populations of farmers that inhabit cattle-range areas in Costa Rica and other countries where bracken growth is dense. Tumors have been demonstrated in rats that were fed the milk of cows that grazed on bracken. However, the dilution resulting from the bulk processing of milk is thought to reduce any risk from milk in most developed countries to negligible levels (Bode and Dong, 2015; Kristanc and Kreft, 2016).

Safrole Safrole (a terpenoid; Fig. 27-9) is typically extracted from the root-bark or the fruit of sassafras plants in the form of sassafras oil. It is also found in a variety of spices, such as cinnamon, nutmeg, black pepper, and herbs such as basil. It was used to flavor root beer and other foods, but was banned by the FDA in 1960 as a food additive. Safrole produces liver tumors in mice and rats by oral administration. The metabolic intermediates of safrole are able to directly react with DNA forming adducts. Safrole is mutagenic and also genotoxic in various in vitro mammalian cell systems. Safrole also induces chromosome aberrations, sister chromatid exchange, and DNA adducts in the liver of rats (EFSA, 2002). In 2011, the National Toxicology Program (NTP) opined that safrole is *reasonably anticipated to be a human carcinogen* based on sufficient evidence of carcinogenicity from studies in experimental animals (NTP, 2011). Safrole is a precursor in the synthesis of the illegal recreational drug methylenedioxymethamphetamine (MDMA) or "Ecstasy." Thus, safrole still poses a potential threat to human health.

Cyanogenic Glycosides Cyanogenic glycosides (nitrogen-containing non-alkaloid) account for approximately 90% of the plant toxins known as cyanogens. The toxicity of cyanogenic glycosides is due to their ability to produce hydrogen cyanide (HCN; also known as prussic acid), which inhibits cellular respiration and causes cytotoxic hypoxia. Many common food plants contain cyanogenic glycosides, such as *linamarin* from cassava, flax seed meal; *amygdalin* (Fig. 27-10) from cherry, apple, and peach. The cyanogenic glycosides are present at negligible levels in the fleshy parts of the fruit. Cases of acute poisoning have been associated with misuse, particularly of preparations from apricot pits, bitter almonds, and cyanide rich apple seeds (http://www.foodsafety.govt.nz/elibrary/industry/Cyanogenic_Glycosides-Toxin_Which.pdf). In parts of Africa, cassava is consumed as a dietary staple. Inappropriate handling and processing of cassava prior to consumption can result in a chronic form of cyanide poisoning termed "tropical ataxic neuropathy," the result of demyelinization of the optic, auditory, and peripheral nerve tracts (Dolan et al., 2010).

Glucosinolates Glucosinolates (nitrogen-containing non-alkaloid) are sulfur-containing goitrogenic glycosides found in Brassicaceae and related families (cruciferous vegetables). Enzymatic hydrolysis of glucosinolates produces several different products, such as isothiocyanates, thiocyanates, oxazolidinethiones, and nitriles. These hydrolysis products contribute to the bitter, hot taste of condiments (mustard, horseradish) and are thought to be responsible for the toxicity of glucosinolate including the goitrogenic or antithyroid activity. Thiocyanate and oxazolidinethione anions compete with iodine in two ways, by inhibiting its uptake by the sodium iodide symporter, and also by the binding of iodine to tyrosine residues of thyroglobulin at high concentrations. Some examples of glucosinolates are *sinigrin*, *dehydroerucin*, and *glucobrassicin* (Fig. 27-11). Glucobrassicin is hydrolyzed to form indole-3-carbinol. Glucosinolate toxicity has been reported in ruminants, poultry, and swine. Poultry, swine, and other non-ruminants can tolerate 5% to 10% rapeseed meal in their diets. Symptoms of poisoning include depressed growth, goiters, enlarged livers, perosis (leg deformity in birds), and poor egg production in chicken (EFSA, 2008a). FDA regulates glucosinolate levels in animal feed—glucosinolate calculated as epi-progoitrin, not more than 4%; goitrin, not more than 0.1%; and nitrile calculated as 1-cyano-2-hydroxy-3-butene, not more than 1.4% (21 CFR 573.310).

Glycoalkaloids (α-Solanine and α-Chaconine) Glycoalkaloids (α-solanine, Fig. 27-12; and α-chaconine) in potato are steroidal glycoalkaloids, which together constitute about 95% of the total glycoalkaloids in the edible potato (*Solanum*

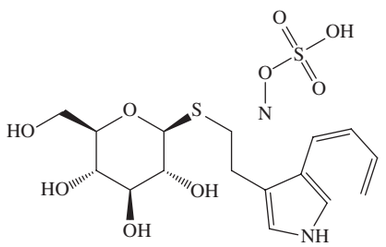

Figure 27-11. *Glucobrassicin.*

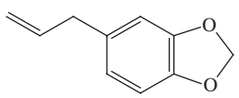

Figure 27-9. *Safrole.*

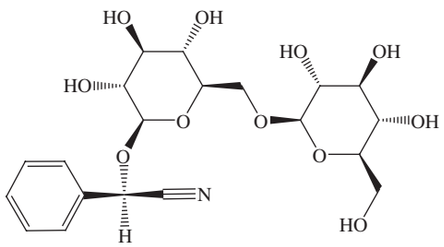

Figure 27-10. *Amygdalin.*

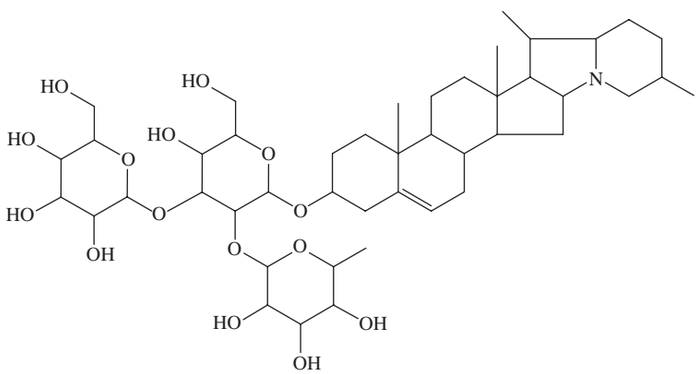

Figure 27-12. *α-Solanine.*

tuberosum). There is usually slightly more α-chaconine than α-solanine. Increases in α-solanine and α-chaconine in the potato peel are closely associated with greening of the peel due to exposure to light, mechanical damage, and improper storage conditions. The α-solanine and α-chaconine each is normally present in amounts less than 5 mg/100 g of tuber fresh weight. Depending on the variety and storage conditions, the concentrations of α-solanine and α-chaconine in potato tubers vary between less than 1 mg and about 25 mg/g potato (Dolan et al., 2010). The content of α-solanine and α-chaconine is not affected much by normal baking, frying, or microwave cooking, but peeling significantly reduces these glycoalkaloids. Acute, short-term, and subchronic animal toxicity studies identified similar adverse effects of α-chaconine, and α-solanine, which is due to their ability to act as inhibitors of acetylcholinesterase and disruptors of cell membranes. Effects on the nervous system included increased heart, pulse, and respiratory rates, sedation, and coma. Effects resulting from cell membrane disruption included internal hemorrhaging, edema, diarrhea, constriction of the abdominal muscles, and lesions of the stomach and duodenum. α-Chaconine is a more potent cholinesterase inhibitor than α-solanine. In some studies, hepatotoxic effects were also induced. It was also determined that the average consumption of glycoalkaloids from potatoes was 12.75 mg glycoalkaloids/person/day (0.18 mg/kg bw based on a bw of 70 kg), which is approximately one-fifth of the lowest dose that has been shown to produce signs of acute toxicity in humans (1 mg/kg bw) (Tice, 1998).

Tannins Tannins are a group of plant phenolics. Tannins are of two types: condensed tannins and hydrolyzable tannins (HT). HTs are polymers of gallic or ellagic acid, and are potentially toxic to ruminants. For example, pyrogallol is a product of HT degradation by ruminal microbes, and has hepatotoxic and nephrotoxic effects (Reed, 1995). Epigallocatechin-3-gallate (EGCG) (Fig. 27-13) and epicatechin gallate (ECG) are the main tannins in green tea. Very high dose of EGCG, such as a single intragastric dose of 1500 mg EGCG/kg, is hepatotoxic in mice (Lambert et al., 2010). Hepatotoxicity in humans has been associated with the consumption of high doses of green tea–containing dietary supplements (10 to 29 mg/kg bw/d) (reviewed by Mazzanti et al., 2009). All cases resolved following cessation of supplement consumption. Based on their analysis, Mazzanti et al. (2009) suggested a causal association between green tea and liver damage, and that the hepatotoxicity was the result of EGCG or its metabolites. Laboratory studies in rodents and dogs using a high bolus dose of green tea–derived preparations rich in EGCG revealed hepatotoxicity and nephrotoxicity (Lambert et al., 2010). However, Isbrucker et al. (2006) demonstrated that dietary administration of EGCG preparation to rats for 13 weeks was not toxic at doses up to 500 mg/kg bw/d. Similarly, no adverse effects were noted when 500 mg EGCG preparation/kg/day was administered to pre-fed dogs in divided doses. The same dose caused morbidity when administered to fasted dogs as a single bolus dose.

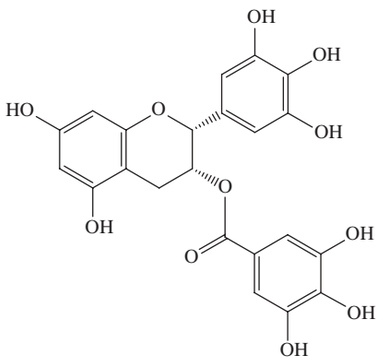

Figure 27-13. *EGCG.*

Furocoumarins Furocoumarins are another group of plant phenolics. Furocoumarins are found mainly in plants belonging to the Rutaceae (e.g., citrus fruits) and Umbelliferae (e.g., parsnip, parsley, celery, carrots) families. Furocoumarins, such as *psoralen* (Fig. 27-14), 5-*methoxypsoralen* (5-MOP, bergapten), and *8-methoxypsoralen* (8-MOP, xanthotoxin or methoxsalen), can form DNA adducts and DNA crosslinks in the presence of UV light (UVA) (320 to 380 nm). The estimated dietary intake of furocoumarins for about 80% of the population is 1.31 mg/day, which is approximately 0.022 mg/kg bw/day for a 60 kg human (Dolan et al., 2010). In humans the phototoxic threshold dose of furocoumarin mixtures is of the order of 10 mg 8-MOP plus 10 mg 5-MOP, which is equivalent to about 15 mg 8-MOP per person (Schlatter et al., 1991). This dose is not reached by the consumption of furocoumarin-containing conventional vegetables under normal dietary habits. Therefore, ordinarily dietary exposure to psoralens is not considered to be a significant risk for the development of photodermatitis, although the margin of safety is low (Schlatter et al, 1991). The 13-week dietary no observable adverse effect level for liver toxicity in the rat (25 mg 8-MOP/kg bw/day) is 1000-fold higher than the estimated dietary intake of furocoumarins in humans. Therefore, the risk of developing liver toxicity in humans due to ingestion of psoralens in the diet is low (Dolan et al., 2010).

Gossypol Gossypol (polyphenolic aldehyde; Fig. 27-15) is a toxic compound found in cotton plants (*Gossypium* sp.). It is concentrated in the cottonseed but is also found in hulls, leaves, and stems. The free form of gossypol is toxic whereas the protein-bound form is relatively nontoxic. The bound form is produced through covalent bonds between gossypol and the free epsilon-amino groups of lysine and arginine. The concentrations of free gossypol contained in feedstuffs such as whole cottonseed and cottonseed meals vary considerably, but gossypol toxicity limits cottonseed use in animal feed. Gossypol poisoning is usually chronic and cumulative. In pigs, poultry, dogs (non-ruminant), pre-ruminants (e.g., young

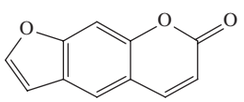

Figure 27-14. *Psoralen.*

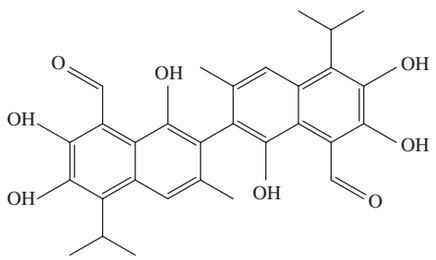

Figure 27-15. *Gossypol.*

calf), and ruminants (e.g., cattle, goat, sheep), the signs of gossypol poisoning are similar and include labored breathing, decreased growth rate, and anorexia. Postmortem findings include generalized edema and congestion of lungs and liver, fluid-filled thoracic and peritoneal cavities, and degeneration of heart fibers. Gossypol also has antifertility effects in many non-ruminant species (Randel et al., 1992). In terms of the severity of toxicity, monogastric animals, such as pigs, birds, and rodents are more susceptible to gossypol toxicity than ruminants. Among ruminants, young ruminants are more sensitive than adult ruminants. However, if the gossypol intake overwhelms the ruminal detoxification capacity, free gossypol may be absorbed at hazardous concentrations even in adult ruminant animals (Gadelha et al., 2014).

Erucic Acid Erucic acid (Fig. 27-16) is a 22-carbon monounsaturated fatty acid with a single double bond at the omega 9 position (C22:1, ω-9). Erucic acid comprises about 30% to 60% of the total fatty acids of rapeseed and mustard seed. The oil extracted from rape (*Brassica napus* or *B. campestris*) and mustard (*Brassica nigra*) seeds have been used in cooking in different parts of the world. Through selective breeding, *B. napus* and *B. campestris* varieties with low erucic acid content were developed in Canada in the 1980s. These improved varieties are popularly known as canola. By definition, canola refers to *B. napus* and *B. campestris* lines containing less than 2% of the total fatty acids as erucic acid. Erucic acid is digested, absorbed, and metabolized like other fatty acids. It undergoes mitochondrial β-oxidation, but is poorly oxidized. Heart muscle seems to be particularly poor at oxidizing erucic acid, which explains the occurrence of myocardial lipidosis in a number of species, such as rat, pigs, and monkeys fed erucic acid in short-term or subchronic studies. Myocardial lipidosis may interfere with the contractile force of heart muscle. Myocardial lipidosis due to erucic acid consumption has not been confirmed in humans, but the results from the animal feeding studies triggered regulatory action in limiting erucic acid exposure in humans (FSANZ, 2003). For example, FDA limits the amount of erucic acid in canola oil to no more than 2% of the component fatty acids (21 CFR 184.1555).

Lectins Lectins are glycoproteins that are known for their ability to agglutinate (clump) cells including erythrocytes in vitro. Hence, lectins are also known as agglutinins (agglutinate cells) and hemagglutinins (agglutinate erythrocytes). Lectins can be found in both plants and animals; those of plant origin are called phytohemagglutinins. Lectins are present in high levels in legumes (e.g., black beans, soybeans, lima beans, kidney beans, and lentils) and grain products. Lectins selectively bind carbohydrates and more importantly, the carbohydrate moieties of the glycoproteins on the surface of most animal cells. High levels of plant lectins in certain improperly cooked food can interfere with nutrient absorption from the intestine and also cause acute GI tract distress. However, not all lectins are toxic, and there are highly toxic lectins without hemagglutinating activity, such as ricin from castor bean. Ricin is one of the most toxic substances known. The seeds of precatory bean *Abrus precatorius* contain the highly toxic lectin *abrin* that has an estimated human fatal dose of 0.1 to 1 μg/kg bw, and has caused death after accidental or intentional poisoning (Wu and Sun, 2012). Less toxic lectins can also be fatal if ingested in high amounts, such as concanavalin A from *Concanavalia ensiformis* (jack bean). Lectins isolated from black beans can produce growth retardation when fed to rats at 0.5% of the diet, and lectin from kidney beans causes death within two weeks when fed to rats at 0.5% of the diet. Soybean lectin produces growth retardation when fed to rats at 1% of the diet (Dolan et al., 2010). Long-term intake of lectins in rodent models shows increased cell turnover, gut hyperplasia, and weight loss. Epithelial cell microvilli are particularly affected by lectin exposure. Areas of epithelial cell necrosis and complete epithelial cell denudation are seen in biopsies of the stomach and intestine. The mechanism of injury of surface-bound lectins may involve inhibition of plasma membrane repair and the exocytosis of mucus that normally accompanies the repair response (Miyake et al., 2007). The combination of soaking and cooking is the best way to reduce the lectin content and its activity in all bean varieties (Nciri et al., 2015).

Phytic Acid (Phytate) Phytic acid (phytate; Fig. 27-17) is inositol hexaphosphate found in edible seeds, nuts, beans/legumes, and grains (mostly in the bran). It serves as the main storage form of phosphorus. When seeds sprout, phytic acid provides the phosphorus needed by the young plant. Ironically, the presence of so many phosphates also enables phytic acid to strongly bind minerals, such as calcium, magnesium, iron, copper, and zinc, making the minerals unavailable for absorption in the intestines. The phytic acid content in plants is highly variable. Phytate has also been shown to inhibit digestive enzymes such as pepsin, trypsin, α-amylase, α-glucosidase. Phytate-rich foods are digested at a slower rate. Several methods reduce the phytic acid content in food, such as fermentation, soaking, germination, and enzymatic treatment of grains with phytase enzyme (Gupta et al., 2015).

Oxalic Acid Oxalic acid (Fig. 27-18) is one of the antinutrients found in the leaves and stems including the corms (underground bulbotubers) of many plants. Some examples include rhubarb, spinach, beet greens, purslane, taro (*Colocasia esculenta*), and many other plants. Ingestion of foods containing high concentrations of oxalic acid results in the formation of insoluble calcium

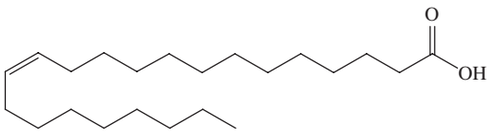

Figure 27-16. *Erucic acid.*

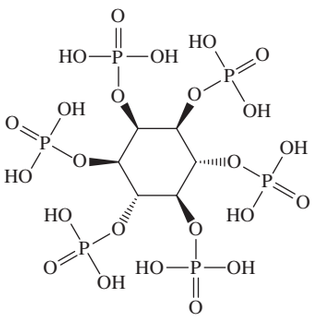

Figure 27-17. *Phytic acid.*

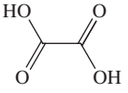

Figure 27-18. *Oxalic acid.*

oxalate and oxalates of other minerals in the systemic circulation. Calcium oxalate precipitates in the kidneys, resulting in renal failure. Sequestration of minerals by oxalate may also decrease their bioavailability, such as reduction in the bioavailability of calcium in the bone. Non-ruminants appear to be more prone to oxalate toxicity than ruminants because rumen bacteria help degrade oxalate. Nevertheless, feeding large amount of oxalate-rich plants at one time may result in oxalate toxicity even in ruminants because the rumen's capacity to degrade oxalate is overwhelmed (Rahman et al., 2013). About 65% of kidney stones consist of calcium oxalate. A randomized controlled trial assigned men with hypercalciuria to follow either a diet low in calcium (400 mg) and oxalate or a diet higher in calcium (1200 mg) with restricted intake of oxalate, protein, and salt. At 5 years, the latter group had a 51% lower rate of stone recurrence than those following a low-calcium diet (Finkelstein and Goldfarb, 2006). Thus, the intake of foods high in oxalate should be limited.

Enzyme Inhibitors Enzyme inhibitors present in many plants (e.g., beans, peas, cereal grains, alfalfa, sunflower, potatoes) and animal foods can inhibit the action of proteases, amylases, and lipases. These inhibitors function as plants' natural defense mechanism against insects and herbivores. For example, kidney beans (*Phaseolus vulgaris*) contain some protease (trypsin and chymotrypsin) inhibitors, and α-amylase inhibitor. The α-amylase inhibitors (α-AI) occur in many plants, and are particularly abundant in cereals. The α-AI inhibits the activity of some mammalian and insect α-amylases, and is a member of a protein family that includes two other defense proteins, phytohemagglutinin and arcelins. These defense proteins are encoded by tightly linked genes. It is likely that this gene family originated from a common ancestral gene through both duplication and divergence (Carlini and Grossi-de-Sá, 2002). Trypsin inhibitor (TI) occurs naturally in many plant-derived foods, notably soybean protein products. Heat treatment inactivates most of the inhibitor activity but 5% to 20% residual inhibitor activity remains. Chronic feeding of food products containing TI can inhibit trypsin and chymotrypsin, stimulate their secretion, cause hypertrophy and hyperplasia of the pancreas, and lead to adenomas and carcinomas of the exocrine pancreas. In the rat, TI promotes pancreatic carcinogenesis initiated by azaserine (Hathcock, 1991). Likewise, most commercially heated soybean meals retain up to 20% of the Bowman–Birk inhibitor (BBI) of chymotrypsin and trypsin, and the Kunitz inhibitor of trypsin (KTI). Toxicology studies in rodents demonstrated that raw soy-based diets had trophic effects on pancreas in rats and hamsters but not in mice. Thus, long-term feeding of raw soy-based diets caused hypertrophy, adenomas, and nodular hyperplasia of the pancreas (Friedman and Brandon, 2001). In contrast, there were no adverse effects on the pancreas of monkeys fed diets containing low levels of trypsin inhibitor for up to 4 years. Specifically, neither pancreatic hypertrophy nor hyperplasia was evident. In addition to monkeys, pancreatic enlargement resulting from the consumption of inhibitors was not observed in dogs, pigs, calves, and baboons (Schneeman and Gallaher, 1986; Friedman and Brandon, 2001). Thus, the consumption of soybeans in amounts normally consumed is unlikely to produce any effect of toxicological significance in humans. Biotin is a coenzyme and a B vitamin (vitamin B7). Biotin acts as a coenzyme of several carboxylase enzymes. Avidin is a tetrameric protein that binds biotin. Avidin is found in raw eggs (egg white) and it binds biotin with a very strong affinity ($K_D \approx 10^{-15}$ M). Thus, consuming raw egg directly or mixing it in other drinks or shakes chronically can cause biotin deficiency. Avidin's ability to bind biotin is largely, but not completely, destroyed by cooking the egg (Durance and Wong, 1992).

Phytoestrogens Phytoestrogens are so named because of their ability to bind to estrogen receptors and stimulate receptor activity. The main groups of phytoestrogen are the lignans, flavonoids (subgroups isoflavones, coumestans, and prenylflavonoids), and stilbenes. Lignans are the main phytoestrogens in a normal diet, and they are found in many cereals, fruits, and vegetables. In vitro assays have shown that most phytoestrogens bind both estrogen receptors (ERs), ERα and ERβ, and activate ER-dependent gene transcription. However, they generally have a higher binding affinity for ERβ. Isoflavones act like selective estrogen receptor modulators (SERMs), such as tamoxifen. Tamoxifen acts as an ER agonist in the uterus and bone but as an antagonist in the breast, where it has proven anticancer activity. In animal models, some phytoestrogens (e.g., isoflavones) produce symptoms of endocrine disruption, which include premature reproductive senescence, compromised fertility, disruption of the lactation and the timing of puberty, the inhibition of sexual behavior, etc. However, the data in humans are not conclusive. The majority of epidemiological studies and meta-analyses concluded that the high intake of soy isoflavones is associated with reduced breast cancer risk in pre- and postmenopausal women. The use of soy isoflavones is seemingly safe in women with a history of breast cancer. Studies even indicate that the isoflavone intake improves the prognosis of breast cancer patients. Thus, the results of the in vitro and animal studies that indicate a potential adverse effect of phytoestrogens are not necessarily corroborated by the findings in humans (Bode and Dong, 2015; Kristanc and Kreft, 2016).

Some Naturally Occurring Toxins in Food of Marine Origin

Toxicity from seafood is due to algal or bacterial toxins that accumulate in shellfish[6] and fish, or due to the production of histamine by spoilage bacteria in fish. These toxin-producing algae are important food source for various shellfish and fish, which accumulate these toxins in specific organs. There are no antidotes for these toxins; they are heat stable and largely unaffected by cooking (Sobel and Painter, 2005). The seafood contaminated with such toxins still look, smell, and taste normal. *Many of these toxins act on sodium channels—some toxins block the channels inducing muscle paralysis; others open the channels, prolong depolarization of the membrane and spontaneous firing causing symptoms like involuntary muscle spasms, tingling paresthesia, etc*. These toxins are usually lethal in small doses.

Saxitoxin Saxitoxin and related toxins are tetrahydropurines mainly produced by the marine dinoflagellate genus *Alexandrium* spp., but also from other dinoflagellate species, such as *Gymnodinium catenatum* and *Pyrodinium bahamense* (Dolan et al., 2010). Saxitoxin causes *paralytic shellfish poisoning* (PSP), which is a severe, rapid onset, life-threatening neurotoxicity caused by the consumption of oysters, mussels, scallops, clams, crustaceans, gastropods, and fish that are contaminated with saxitoxin or closely related marine toxins. *Saxitoxin inhibits the conduction of nerve impulse by blocking the sodium channels* (Daranas et al., 2001). Symptoms of PSP, such as headache, nausea, vomiting, and diarrhea, appear within 30 minutes. In fatal cases respiratory arrest occurs 2 to 12 hours following consumption of the contaminated shellfish. Using the available human data on intoxication in humans

[6]Edible shellfish include two groups: crustaceans and mollusks. Common crustaceans include lobster, crab, crawfish (crayfish), prawn, and shrimp. Common mollusks include clam, mussel, oyster, scallop, squid, and octopus.

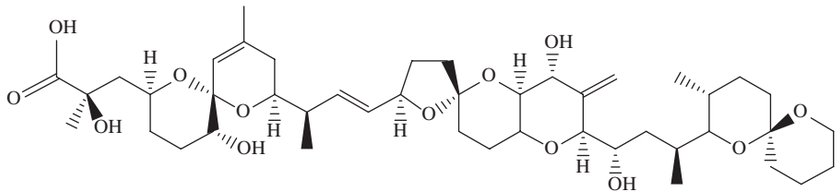

Figure 27-19. *Okadaic acid.*

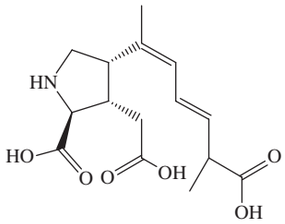

Figure 27-20. *Domoic acid.*

comprising more than 500 individuals, EFSA CONTAM Panel determined a LOAEL of 1.5 μg saxitoxin equivalents/kg bw. Using the uncertainty factor of 3, an ARfD of 0.5 μg saxitoxin equivalents/kg bw was established (EFSA, 2009a). The rationale for using 3 as the safety factor was the fact that documentation of human cases included a large number of affected consumers, including sensitive individuals, and the fact that saxitoxin-induced mild illness is readily reversible. It was determined that in order for a 60 kg adult to avoid exceeding the ARfD of 0.5 μg saxitoxin equivalents/kg bw, there should not be more than 75 μg saxitoxin equivalents/kg of shellfish meat. The EFSA CONTAM Panel recommended significant reduction of the current European Commission (EC) limit of PSP, which is 800 μg/kg (= 80 μg/100 g) of shellfish meat. The FDA consumer guidance recommends that the limit of the saxitoxins in shellfish meat should not exceed 0.8 ppm saxitoxin equivalents, that is, 80 μg saxitoxin equivalents/100 g shellfish meat (FDA, 2011a).

Okadaic Acid (OA), Dinophysistoxin (DTX), Pectenotoxin (PTX), Yessotoxins (YTX) Okadaic acid (OA) (Fig. 27-19), dinophysistoxin (DTX), pectenotoxin (PTX), and yessotoxins (YTX) are lipophilic polyether compounds that all cause *diarrheic shellfish poisoning* (DSP), which is a rapid-onset but self-resolving illness involving the GI system. The toxins are produced by marine dinoflagellates of the genus *Dinophysis* spp. These toxins are known to accumulate in marine shellfish, particularly in the hepatopancreas (Paredes et al, 2011; Reguera et al., 2014). DSP has been reported more often in Japan but also in Europe. OA strongly inhibits the eukaryotic serine/threonine phosphatases 1 and 2A, resulting in hyperphosphorylation of many cellular proteins. *It has been proposed that OA-induced stimulation of phosphorylation of proteins that control sodium secretion by intestinal cells results in diarrhea*. Symptoms of DSP, such as diarrhea and abdominal cramps, usually appear within 30 minutes after exposure but typically resolve within 3 to 4 days. These are not considered to be lethal (Paredes et al, 2011; Valdiglesias et al., 2013). An intake of 40 μg of OA equivalents is the minimum dose required to produce DSP symptoms in human adults. The lowest observed adverse effect level (LOAEL) in mice, by acute oral administration, was calculated to be 75 μg/kg bw. Human data indicate a LOAEL of 1.0 to 1.6 μg/kg bw (Valdiglesias et al., 2013). EFSA concluded that the LOAEL for human illness is approximately 50 μg OA equivalents/person, which is equivalent to 0.83 μg OA equivalent/kg bw for a 60-kg person (EFSA, 2008b). The FDA consumer guidance recommends that the limit of the total OA in shellfish meat should not exceed 0.16 ppm, that is, 16 μg of total OA/100 g shellfish meat (FDA, 2011a).

Domoic Acid (DA) Domoic acid (DA) (Fig. 27-20) is a water-soluble, heat-stable amino acid that causes *amnesic shellfish poisoning* (ASP). DA is produced by marine diatoms (algae) of the genus *Pseudonitzschia* spp., and by marine red algae of the genus *Chondria* spp., particularly when there are severe algal blooms. Because DA toxicity does not always involve amnesia, it is also known as *domoic acid poisoning* (Paredes et al, 2011). Symptoms of ASP included vomiting, nausea, diarrhea, and abdominal cramps within 24 hours of ingestion; neurological symptoms developed within 48 hours. Both shellfish and fish can accumulate DA without apparent ill effects. In mammals including humans, *DA is neurotoxic; high levels of DA cause seizures. DA specifically targets the hippocampus*. DA is structurally similar to but 2 to 3 times more potent than another known neurotoxin kainic acid (KA) found in marine seaweed. Both DA and KA are excitatory amino acid analogues of glutamic acid, and they act through the ionotropic glutamate receptors (GluR), preferentially the KA subtype of GluR (Pulido, 2008). Hyperexcitation of the receptors leads to hyperexcitation of the neurons which ultimately "burn out" and die off. The damage of hippocampal neurons results in permanent loss of the "short-term memory" in susceptible individuals (hence the name amnesic shellfish poisoning). The toxicological database for DA comprises mostly studies on the acute toxicity in rodents and cynomolgus monkeys. Neurotoxicity is the critical toxicological effect identified in experimental animals as well as in humans (EFSA, 2009b). Using the human DA poisoning acute toxicity data, EFSA (2009b) determined the ARfD to be 30 μg DA/kg bw. This ARfD was derived by applying an overall uncertainty factor of 30 to the lowest-observed-adverse-effect-level (LOAEL) for mild signs and symptoms, which was 0.9 mg/kg bw. The basis for the uncertainty factor 30 was a factor of 3 for the extrapolation of LOAEL to NOAEL multiplied by a factor of 10 to account for inter-individual variability in humans. The FDA consumer guidance recommends that the limit of DA in shellfish meat should not exceed 20 ppm except in the viscera of Dungeness crab, where it should not exceed 30 ppm (FDA, 2011a). A 20 and 30 ppm DA are equivalent to 2 mg DA/100 g and 3 mg/100 g of shellfish meat, respectively.

Brevetoxins Brevetoxins are a family of lipophilic cyclic polyether toxins that cause *neurotoxic shellfish poisoning* (NSP), which involves transient GI and neurological symptoms. Brevetoxins are produced by the marine dinoflagellate *Karenia brevis* (formerly known as *Gymnodinium breve*) (Watkins et al., 2008). *Brevetoxins open voltage-gated sodium channels causing uncontrolled Na^+ influx into the cell, prolonged depolarization of neuronal and muscle cell membranes, and spontaneous firing*. The GI symptoms

of NSP include vomiting, diarrhea, and pain in the abdomen. Neurological symptoms include paresthesia (a pricking, tingling sensation), reversal of hot and cold perception, vertigo (false sense of motion), and ataxia (involuntary muscular movement, or spasms). Symptoms typically occur within 30 minutes to a couple of hours after consuming contaminated shellfish and typically resolve within 2 days. The toxicological database for brevetoxins is limited, and comprises only studies on their acute toxicity following intravenous (i.v.), intraperitoneal (i.p.), and oral administration (EFSA, 2010). Because brevetoxins are lipophilic, they pass through cell membranes including the blood–brain barrier. Brevetoxins are rapidly absorbed and distributed throughout the body, and are metabolized in the liver. They are primarily removed in the bile within the first 48 hours, but urinary excretion plays a role after this time as well (Watkins et al., 2008). The LD50 of different brevetoxins may vary widely and the route of administration also plays a major role. For example, the oral LD50 in mice for brevetoxin-2 is 6600 mg/kg bw and for brevetoxin-3 is 520 mg/kg bw. In contrast, i.v. and i.p. administration causes toxic signs including death almost immediately, whereas toxic signs including death occurred approximately after 5 hours after oral administration (EFSA, 2010). EFSA (2010) concluded that there were insufficient human and animal toxicity data to complete a risk assessment. The FDA consumer guidance recommends that the limit of the brevetoxins in shellfish meat should not exceed 0.8 ppm brevetoxin-2 equivalents, that is, 80 μg brevetoxin-2 equivalents/100 g shellfish meat (FDA, 2011a).

Ciguatoxin Ciguatoxin group of toxins include ciguatera toxin, gambiertoxin, and maitotoxin. They occur in marine fishes. Ciguatoxins are mostly lipophilic, heat-stable polyethers. They are produced by the benthic dinoflagellate *Gambierdiscus toxicus*. Gambiertoxin produced by the dinoflagellate is biotransformed by the fish to produce ciguatera toxin. These dinoflagellates are consumed by small herbivorous fishes that are, in turn, consumed by large carnivorous fishes (e.g., barracuda and grouper fish), resulting in bioconcentration of the toxin along the food chain (Lehane and Lewis, 2000). Ciguatoxins cause *ciguatera fish poisoning* (CFP), which is primarily associated with the consumption of large predatory fishes that have accumulated ciguatoxins by feeding on smaller contaminated fishes. *Ciguatoxins open voltage-gated sodium channels at the neuromuscular junction, resulting in membrane hyperexcitability, spontaneous repetitive neurotransmitter release, blockage of synaptic transmission, and depletion of synaptic vesicles*. Maitotoxin is water-soluble and it opens calcium channels of the cell plasma membrane; it is the most toxic nonproteinaceous molecule known (Lehane and Lewis, 2000; Daranas et al., 2001). CFP is typically a self-limiting illness, although symptoms may last for months and deaths have been reported. Symptoms of CFP include GI (e.g., vomiting, diarrhea, nausea), neurological (e.g., tingling, itching), and cardiovascular (e.g., hypotension, bradycardia) effects. In severe cases the symptoms may begin as soon as 30 minutes after ingestion of contaminated fish, while in milder cases they may be delayed for 24 to 48 hours. Symptoms may last even for months and the administration of mannitol within 24 hours of consumption relieves some symptoms (Dickey and Plakas, 2010). CFP is currently the most common type of marine biotoxin food poisoning with an estimated number of 10,000 to 50,000 people affected annually (Lehane, 2000). The FDA consumer guidance recommends that the limit of ciguatoxins in fish flesh should not exceed 0.01 ppb (0.01 μg/kg fish flesh) for Pacific ciguatoxin, and 0.1 ppb (= 0.1 μg/kg fish flesh) for Caribbean ciguatoxin (FDA, 2011a).

Tetrodotoxin Tetrodotoxin is a heat-stable, water-soluble molecule produced by symbiotic bacteria concentrated in the liver and gonad of puffer fish (Fugu), and in many other marine organisms. *Tetrodotoxin is a potent sodium channel blocker; it reduces the membrane excitability and blocks the conduction of nerve impulse, thereby causing muscle paralysis*. Symptoms of toxicity include perioral paresthesia (burning or prickling sensation) that may spread to the entire body, and could be followed by vomiting, lightheadedness, dizziness. In non-fatal poisoning, symptoms usually begin within 30 minutes after exposure and completely resolve within 24 hours after onset. In fatal cases, progression is precipitous, with death due to respiratory muscle paralysis occurring within 6 hours after onset of symptoms. In Japan, puffer fish is a delicacy but it is cleaned and prepared by specially trained chefs. The intragastric LD50 of tetrodotoxin in mouse was 532 μg/kg (Lago et al., 2015). Even though tetrodotoxin is such a potent sodium channel blocker, it cannot block the sodium ion channel of puffer fish because these sodium channels are insensitive to tetrodotoxin.

Scombroid Toxicity Scombroid toxicity causes *scombroid fish poisoning*. Scombroid poisoning is unique among the seafood toxins because it results from product mishandling rather than contamination from other trophic levels (Hungerford, 2010). *It is mostly caused by the consumption of fish (Scombroidae family) with high histamine levels, such as tuna, mackerel, blue fish, sardines, anchovies,* and *mahi-mahi. Symptoms are essentially the same as those associated with histamine toxicity. Thus, such histamine-induced reactions are often misdiagnosed as IgE-mediated fish allergy.* If the fish with high levels of tissue histidine are not refrigerated properly, the bacteria proliferate and convert the tissue histidine into histamine, which is heat-stable. In most cases, histamine levels in illness-causing fish have been above 200 ppm, often above 500 ppm (FDA, 2011a). Symptoms of toxicity include tingling and burning sensations around the mouth, headache, facial flushing, palpitations, profuse sweating, truncal rash and pruritis, abdominal cramps, nausea, and diarrhea. In most people, these symptoms are self-limiting, but circulatory collapse, shock, and acute pulmonary edema have been described in severe cases (Kerr and Parke, 1998; Becker et al., 2001). Scombroid poisoning is the most common cause of ichythyotoxicosis worldwide. Because more than 80% of fish consumed in the United States is now imported from other countries, the disease is intimately linked with the global fish trade (Feng et al., 2016).

Palytoxin Palytoxin is produced by the zoantharians of the genus *Palythoa* (cnidarians found in coral reefs). Fishes and crabs living in close association with or eating this mass may become contaminated with palytoxin. Palytoxin has been reported in mackerel, parrotfish, and several species of crabs. It is one of the most lethal marine toxins known. *It binds to the Na^+/K^+-ATPase (Na^+/K^+ pump) and turns it into a nonspecific ion channel. This results in K^+ efflux, Na^+ influx, and prolonged membrane depolarization*. Victims exposed to palytoxin report nausea, vomiting, and diarrhea. Within several hours, symptoms include myoglobinuria, a burning sensation around the mouth and extremities, muscle spasms, paresthesia, bradycardia, dyspnea (labored breathing), and dysphonia (difficulty in speaking). Cause of death may be the result of myocardial injury. Palytoxin is known in vitro to be a powerful hemolysin. The Na^+/K^+-ATPase inhibition by palytoxin is similar to that of ouabain, but unlike ouabain, palytoxin has no effect on H^+-, Ca^{2+}-, or H^+/K^+-ATPases (Ramos and Vasconcelos, 2010; Kotsonis and Burdoch, 2013).

Some Microbial Contaminants in Food

Food-related illnesses resulting from microbial contamination can pose a serious threat to public health. Foodborne disease outbreaks are tracked by the Centers for Disease Control and Prevention (CDC). CDC estimates that each year roughly 1 in 6 Americans (or 48 million people) gets sick, 128,000 are hospitalized, and 3000 die of

foodborne diseases. The 2014 CDC annual report on the surveillance for foodborne disease outbreaks in the United States reports that there were 864 outbreaks involving bacterial, viral, parasitic, chemicals, and toxin etiology. However, the actual frequency may be significantly higher because (1) an outbreak is classified as such only when the source can be identified as affecting two or more people and (2) most home poisonings are mild or have a long incubation time and are therefore not connected to the ingested food, and go unreported.

Food can serve as the vector for the transfer of microbial toxins or live pathogenic microbes into the human GI tract. Bacterial toxins are of two types: exotoxin and endotoxin. *Exotoxins* are not an integral part of the bacterial membrane; they are soluble, usually heat-labile proteins found in the cytoplasm, and are easily secreted into the surrounding medium, usually by gram-positive bacteria. Exotoxins enhance bacterial virulence, and are further subdivided according to their mode of action, such as emetic toxins that trigger severe vomiting; enterotoxins that cause diarrhea; cytotoxins that kill host cells; neurotoxins that interfere with normal transmission of nerve impulse. Table 27-10 lists some important foodborne bacterial exotoxins and their mode of action in causing toxicity. In contrast, *endotoxins* are lipopolysaccharides and membrane constituents. Endotoxins are not secreted but released from dead or dying gram-negative bacteria. Humans have background exposure to endotoxins by the oral and inhalation route, which may vary significantly depending on the living and working conditions (Madsen, 2006; Inagawa et al., 2011). However, higher-than-tolerable exposure to endotoxins can be problematic. Endotoxins are pyrogenic and are not easily destroyed. Endotoxins also stimulate inflammatory responses. Some bacteria, such as *Shigella* spp., *Staphylococcus aureus*, or *Escherichia coli*, can elaborate both endotoxin and exotoxin.

The FDA Bad Bug Book, which is available to the public, provides current information about the major known agents that

Table 27-10

Some Foodborne Bacterial Exotoxins and Their Mode of Action

BACTERIAL EXOTOXIN	PRODUCING ORGANISM	TOXICITY TO THE HOST	MODE OF ACTION
Cereulide (emetic toxin)	*Bacillus cereus*	Vomiting (emesis)	Toxin binds to the 5-HT3 receptors in the stomach/small intestine and stimulates the vagus nerve. Stimulation of the afferent vagal neurocircuit triggers the vomiting center in the hindbrain
Cholera toxin (enterotoxin)	*Vibrio cholerae*	Diarrhea	Stimulates the efflux of ions and water from intestinal epithelial cells. The mechanism involves overstimulation of G proteins which results in persistent activation of adenylate cyclase to produce cAMP. Very high levels of intracellular cAMP prolong the opening of membrane channels that cause the efflux of Cl^- and other ions and water from the infected cells
Staphylococcal enterotoxin (superantigen)	*Staphylococcus aureus*	Vomiting and diarrhea	Stimulates the vomiting center in the brain. Penetrates the gut lining and also activates immune response in the gut. The inflammatory response and the released inflammatory mediators are associated with inflammatory injury to the GI tract, and electrolyte dysregulation
Listeriolysin O (enterotoxin)	*Listeria monocytogenes*	Diarrhea	Pore-forming cytolysin that directly binds to the membranes in a cholesterol-dependent manner, which is followed by oligomerization of monomers, and formation of pores of 20- to 30-nm diameter that facilitate the efflux of ions and water
CPE (enterotoxin)	*Clostridium perfringens*	Diarrhea	Pore-forming cytolysin. Binds to the claudin receptors (tight junction membrane proteins) on enterocytes, forms large complex that forms pores in the membrane, causes a strong influx of calcium, and apoptotic cell death. Enterocyte death disrupts villus integrity, and causes intestinal damage and electrolyte dysregulation
Diphtheria toxin (cytotoxin)	*Corynebacterium diphtheriae*	Cytotoxicity (cell death)	Inhibits protein synthesis by inhibiting the eukaryotic elongation factor 2 (eEF2)
Shiga toxin (cytotoxin)	*Shigella dysenteriae*; shiga toxin–producing *Escherichia coli* (STEC)	Cytotoxicity (cell death)	Inhibits protein synthesis by inhibiting 28S ribosomal RNA (28S rRNA). The same mechanism is also utilized by ricin in castor beans
Botulinum toxin (neurotoxin)	*Clostridium botulinum*	Neurotoxicity	Interferes with normal transmission of nerve impulse by blocking neurotransmitter (e.g., acetylcholine) release at the nerve terminals

SOURCES: Schmitt et al. (1999), Dramsi and Cossart (2002), Pinchuk et al. (2010), and Kotsonis and Burdoch (2013).

cause foodborne illness. The information provided in the book is abbreviated and general in nature, and is intended for practical use. It is not intended to be a comprehensive scientific or clinical reference. In the following narrative, a few of the microbial contaminants in food are briefly discussed. The FDA Bad Bug Book can be accessed at: http://www.fda.gov/downloads/Food/FoodborneIllnessContaminants/UCM297627.pdf.

Clostridium botulinum, C. butyricum, and C. baratti Food botulism is caused by eating foods contaminated with botulinum toxins. Foods associated with botulinum toxin include improperly canned low-acid foods (e.g., green beans, corn, beets, asparagus, chili peppers, mushrooms, spinach, figs, baked potato, cheese sauce, beef stew, olives, and tuna). The toxin also may occur in smoked fish, fermented food (e.g., seal flippers, salmon eggs), and improperly home-cured hams. An increasing source of poisonings is from the use of flavored oils or oil infusion, most typically in garlic-in-oil preparations. All Clostridia are gram-positive, spore-forming anaerobes, and they produce a total of seven serotypically and antigenically distinct botulinum neurotoxins (serotypes A–G) (Rossetto et al., 2014). Human botulism is caused mainly by types A, B, E, and (rarely) F. Types C, D, and also E cause toxicity in other mammals, birds, and fish (WHO, 2013). Type G has not caused any human illness. Botulinum toxin is neurotoxic that interfere with neural transmission by blocking the release of acetylcholine at peripheral nerve endings, causing muscle paralysis. The toxin is elaborated in foods, wounds, and infant gut. Clinical illness is characterized by cranial nerve palsies, followed by descending flaccid muscle paralysis, which can involve the muscles of respiration. Recovery often takes weeks to months (Sobel et al., 2004). The toxins are heat-labile (may be rendered harmless at 80°C to 100°C for 5 to 10 minutes) but the spores are among the most heat-resistant. The case fatality rate in the United States is 4% (Sobel et al., 2004) and the poison is fatal in 3 to 10 days; the lethal dose is approximately 1 ng. Whereas a proteolytic strain of *C. botulinum* (Group I) may cause the food to appear and smell "spoiled" (by-products include isobutyric acid, isovaleric acid, and phenylpropionic acid), this is not the case with nonproteolytic strains, many of which can flourish and elaborate toxin at temperatures as low as 3°C. Current methods for detecting botulinum toxin include a mouse bioassay and an enzyme-linked immunosorbent assay, with the mouse bioassay being the accepted standard. The successful use of nitrates in meat to prevent spoilage by *C. botulinum* resulted in the petitioning of FDA by the USDA to have sodium and potassium nitrate approved for use by "prior sanction" (21 CFR 181.33) (Kotsonis and Burdoch, 2013).

Clostridium perfringens The primary reservoir for *C. perfringens* is the intestinal tract of warm-blooded animals (including humans). Most incidences of *C. perfringens* food poisoning are associated with the consumption of roasted meat that has been contaminated with intestinal contents at slaughter, followed by roasting and inadequate storage. This allows *C. perfringens* growth and the elaboration of *C. perfringens* enterotoxin (CPE). Virtually all food poisoning is produced by type A strain, although a particularly severe form (a necrotic enteritis called "pig-bel" among indigenous peoples of the New Guinea highlands or in Germany known as "Darmbrand") is produced by the type C strain, which has a mortality rate of 15% to 25% even with treatment. The toxin is normally trypsin-sensitive, but people with low intakes of protein or who consume trypsin-inactivating foods (e.g., sweet potatoes) are more at risk than those with normal trypsin levels (Granum and Brynestad, 1999; Granum, 2006). CPE is enterotoxic and follows an ordered series of events, first causing cellular ion permeability, followed by inhibition of macromolecular (DNA, RNA) synthesis, morphological alteration, cell lysis, and villi tip desquamation and severe fluid loss. This is manifested by abdominal cramping and diarrhea; diarrhea occurs within 8 to 16 hours. However, symptoms are of short duration, one day or less. Foods associated with *C. perfringens* poisoning include cooked meat or poultry, gravy, stew, and meat pies. *C. perfringens* is also associated with the production of 11 other toxins, including those associated with gas gangrene (Crane, 1999; Kotsonis and Burdoch, 2013).

Bacillus cereus *B. cereus* produces one emetic toxin and three different enterotoxins. The emetic toxin (a cyclic oligopeptide) is pre-formed in food, and the enterotoxins (proteins) are produced in the small intestine of the host (Granum and Lund, 1997). *B. cereus* is a Gram-positive, spore-forming rod, but is an aerobe or facultative anaerobe. *B. cereus* is a causative agent of emetic or diarrheagenic enterotoxins elaborated in food. The emetic thermostable toxin (surviving 259°F for 90 minutes) is called cerulide (a small cyclic peptide, 1.2 kDa, that acts on 5-HT3 receptors stimulating the vagus afferent nerve) and is produced by serotypes 1, 3, and 8; it is also resistant to pH and proteolysis, but is not antigenic. The diarrheagenic thermolabile toxin (surviving 133°F for 20 minutes) is produced by serotypes 1, 2, 6, 8, 10, and 19 and may also be produced in situ in the lower intestine of the host. The diarrheal form may actually consist of three toxins, one of which is hemolytic (Granum, 2006). Foods associated with this organism and its toxic properties include boiled and fried rice (principally the emetic form), while the diarrheal form has a wider occurrence and may be found in meats, stews, pudding, sauces, dairy products, vegetable dishes, soups, and meat loaf (Granum and Lund, 1997; Crane, 1999). The foods associated with the two types somewhat reflect the geographic distribution of the types. For example, the emetic type predominates in Japan, whereas in North America and Europe, the diarrhea type is most often seen. Evidence is accumulating that other species of *Bacillus* may elaborate food toxins, including *B. thuringiensis*, *B. subtilis*, *B. licheniformis*, and *B. pumilis* (Crane, 1999; Granum, 2006). A notable exception is *B. cereus* var toyoi, a naturally occurring, nontoxigenic, and nonpathogenic strain. This has been approved for addition to swine, bovine, poultry, and rabbit feed in the European communities (Kotsonis and Burdoch, 2013).

Staphylococcus aureus Staphylococcal intoxication includes staphyloenterotoxicosis and staphylococcus food poisoning. *S. aureus* produces a wide variety of exotoxins, including toxic shock syndrome toxin-1 (TSST-1), the exfoliative toxins ETA and ETB, leukocidin, and the staphylococcal enterotoxins A–I (SEA–SEI). SEA is the most common toxin in staphylococcus-related food poisoning. Although enterotoxemia only develops from ingestion of large amounts of SE, emesis is produced as the result of stimulation of the putative SE receptors in the abdominal viscera, followed by a cascade of inflammatory mediator release. All the SE toxins cause emesis and gastroenteritis in primates but the induction of emesis is not directly correlated to superantigenic activity (Granum, 2006). Sources of *Staphylococcus* include nose and throat discharges, hands and skin, infected cuts, wounds, burns, boils, pimples, acne, and feces. The anterior nares of humans are the primary reservoirs. Other reservoirs include mastitis in the udders of cows and ewes (responsible for contamination of unpasteurized milk) and arthritic and bruised tissues of poultry. Foods usually are contaminated after cooking by persons cutting, slicing, chopping, or otherwise handling them, and then keeping them at room temperature for several hours or storing them in large containers. Foods associated with staphylococcal poisoning include cooked ham, meat products including poultry and dressing, sauces and gravy, cream-filled pastry, potatoes, ham, poultry, fish salads, milk, cheese, bread pudding, and generally high-protein leftover foods (Kotsonis and Burdoch, 2013).

Escherichia coli Enterohemorrhagic *E. coli* (EHEC) serotype O157:H7 is a human pathogen responsible for outbreaks of bloody diarrhea and hemolytic uremic syndrome worldwide. There are four main categories of *E. coli* associated with diarrheal disease: enteropathogenic, enterotoxigenic, enteroinvasive, and verocytotoxin-producing *E. coli* (VTEC). VTEC includes "shiga toxin"–producing *E. coli* (STEC) and "shiga-like toxin"–producing *E. coli*. EHEC is a serotype of VTEC. The reference to shiga toxin is the result of the clinical similarity of the bloody diarrhea caused by EHEC to that caused by *Shigella*. The symptoms of *E. coli* STEC infections vary, but commonly include severe stomach cramps, diarrhea (often bloody), and vomiting, and about 5% to 10% of those diagnosed with STEC infections develop hemolytic uremic syndrome, a potentially life-threatening complication because the kidneys may stop working. Cattle are a significant reservoir of *E. coli* O157:H7. Hence, most outbreaks in the United States have been associated with hamburgers and other beef products, although raw vegetables (often fertilized with manure) and unpasteurized apple cider and juice have been reported as sources of outbreaks. Outbreaks in Europe are more often associated with contamination of recreational waters (swimming pools, lakes, etc.). Other sources of contamination include person-to-person contact (especially in families and among institutionalized persons) and contact with farm animals especially following educational farm visits (Karch et al., 1999). Human cases of *E. coli* O157:H7 infections have been reported from the consumption of contaminated lettuce, potatoes, radish sprouts, alfalfa sprouts, cantaloupe, and unpasteurized apple cider and juice (Karch et al., 1999; Kotsonis and Burdoch, 2013).

Like the diarrhea-causing *E. coli*, *Shigella* spp. (*S. dysenteriae, S. flexneri, S. boydii*, and *S. sonnei*) cause an estimated 165 million cases of *Shigella* diarrhea annually, over 90% of which is in developing countries resulting in over a million deaths annually (Niyogi, 2005). Contamination of food by unhygienic food handlers and consumption of raw vegetables raised in contaminated soils are two main contributors to the incidence of *Shigella* diarrhea.

Listeria monocytogenes *L. monocytogenes* is the causative agent for Listeriosis. *L. monocytogenes* is a gram-positive bacillus found in soil, water, and some animals, including poultry and cattle. It can be present in dairy products, poultry, meat, salads, etc. Food products can be contaminated by contact with soil, feces, discharges, and urine from infected animals and humans. *Listeria* can also live in food processing plants and contaminate a variety of processed foods. *Listeria* can grow even in the refrigerator, but is killed by cooking and pasteurization. The populations that are particularly at risk from *L. monocytogenes* infection include older adults, pregnant women, infants, immunocompromised individuals, organ transplant patients, and people with certain diseases. Listeriosis in pregnant women can result in abortion, fetal death, or premature birth. Listeriosis has a low incidence of infection, although this is undeniably increasing, with a high fatality rate among those infected (Mateus et al., 2013). Since 2008, several Listeriosis outbreaks have been linked to diverse types of fresh produce: sprouts, celery, cantaloupe, stone fruit, and apples. The 2011 cantaloupe-associated outbreak was one of the deadliest foodborne outbreaks in recent U.S. history (Garner and Kathariou, 2016). In 2008, FDA issued a draft guidance for the industry that contains nonbinding recommendations for the control of *L. monocytogenes* in refrigerated or frozen ready-to-eat foods (FDA, 2008). In the recent past there have been multiple reports of food-related Listeria outbreaks in the United States.

Salmonella sp. *Salmonella enterica* serotype Enteritidis is of great public health concern. *Salmonella* sp. in food can cause salmonellosis. Feces of infected humans, animals, and birds containing *Salmonella* can contaminate raw fruits and vegetables as well as meat and milk products. Consuming contaminated food causes nausea, vomiting, abdominal cramps, diarrhea, fever, and headache. The interval between exposure and the onset of the symptoms may be as short as a few hours or it can take a couple of days. The illness is generally self-limiting for people with intact immune system and is resolved within a week. Mortality is rare but occurs in the very young and the very old and in immunocompromised individuals (Coburn et al., 2007). FDA issued a final rule in 2009 that requires shell egg producers to implement measures to prevent *Salmonella* Enteritidis from contaminating eggs on the farm and from further growth during storage and transportation (FDA, 2009). In the recent past there have been several multistate foodborne outbreaks involving *Salmonella*.

Cronobacter sakazakii (Enterobacter sakazakii) *C. sakazakii* was previously known as *E. sakazakii*. *C. sakazakii* is found in milk powder, rice, vegetables, cheese, sausage meat, teas, and various spices. *C. sakazakii* has also been identified in the hospital environment in association with infant bottle brushes and food preparation equipment, such as blenders. Most of the attention to *C. sakazakii*–related contamination of food products has focused on powdered infant formula. In 2002, FDA published a warning regarding the presence of *C. sakazakii* in infant formula (Hunter et al., 2008). This bacterium is an emerging opportunistic pathogen that is associated with rare but life-threatening cases of meningitis, necrotizing enterocolitis, and sepsis in premature and full-term infants. Infants aged less than 28 days are considered to be most at risk (Drudy et al., 2006).

Some Foodborne Molds and Mycotoxins

Molds have served humans for centuries in the production of foods (e.g., ripening cheese) and have provided various fungal metabolites with important medicinal uses; they also may produce secondary metabolites with the potential to produce severe adverse health effects, including behavioral changes (Cousins et al., 2005). Frank growth of fungi on animal hosts produces *mycoses*, whereas dietary, respiratory, dermal, and other exposures to toxic fungal metabolites produce *mycotoxicoses*. In the context of food toxicology, a discussion of mycotoxins and the mycotoxicosis they cause is more relevant. Mycotoxins are secondary fungal metabolites (i.e., not essential for survival of the mold) secreted into the microenvironment around the mold. Mycotoxins represent a diverse group of chemicals that can occur in a variety of plants used as food, including commodities such as cereal grains (barley, corn, rye, wheat), coffee, dairy products, fruits, nuts, peanuts, and spices. A few mycotoxins also can occur in animal products derived from animals that consume contaminated feed (e.g., milk). However, because commodities are consumed in great amounts, the mycotoxins present in these foods represent the greatest risk (Cousins et al., 2005).

Data from animal studies indicate that the consumption of food contaminated with mycotoxins has the potential to contribute to a variety of human diseases (Miller, 1991). Reports of acute intoxications are few (e.g., consumption of wild *Amanita* mushroom and α-amanitin poisoning); however, prolonged exposure to small quantities of mycotoxin may lead to more deleterious effects including growth retardation, birth defects, impaired immunity, decreased disease resistance, and tumor formation in humans and decreased production in farm animals (CAST, 2003). Importantly, the presence of a toxigenic mold does not guarantee the presence of a mycotoxin, which is elaborated only under certain conditions. Although there are many different mycotoxins and subgroups (Table 27-11), this discussion will focus on aflatoxins, trichothecenes, fumonisins, ochratoxin A, and ergot alkaloids.

Table 27-11

Selected Mycotoxins Produced by Various Molds and Some of Their Effects and Commodities Potentially Contaminated

MUCOTOXIN	SOURCE	EFFECT	COMMODITIES CONTAMINATED
Aflatoxins B1, B2, G1, G2	*Aspergillus flavus*, *A. parasiticus*	Acute aflatoxicosis, carcinogenesis	Corn, peanuts, and others
Aflatoxin M1	Metabolite of AFB1	Hepatotoxicity	Milk
Fumonisins B1, B2, B3, B4, A1, A2	*Fusarium verticillioides*	Renal and liver carcinogenesis	Corn
Trichothecenes (e.g., T-2, deoxynivalenol, diacetoxyscirpenol)	*Fusarium*, myrothecium	Hematopoietic toxicity, meningeal hemorrhage of brain, "nervous" disorder, necrosis of skin, hemorrhage in mucosal epithelia of stomach and intestine, emesis, feed refusal, immune suppression	Cereal grains, corn
Zearalenones	*Fusarium*	Estrogenic effect	Corn, grain
Cyclopiazonic acid	*Aspergillus*, *Penicillium*	Muscle, liver, and splenic toxicity	Cheese, grains, peanuts
Kojic acid	*Aspergillus*	May be hepatotoxic?	Grain, animal feed
3-Nitropropionic acid	*Arthrinium sacchari*, *A. saccharicola, A. phaeospermum*	Central nervous system impairment	Sugarcane
Citreoviridin	*Penicillium citreoviride*, *P. toxicarium*	Cardiac beriberi	Rice
Cytochalasins E, B, F, H	*Aspergillus*, *Penicillium*	Cytotoxicity	Corn, cereal grain
Sterigmatocystin	*Aspergillus versiolar*	Carcinogenesis	Corn
Penicillinic acid	*Penicillium cyclopium*	Nephrotoxicity, abortifacient	Corn, dried beans, grains
Rubratoxins A, B	*Penicillium rubrum*	Hepatotoxicity, teratogenic	Corn
Patulin	*Penicillium patulum*	Carcinogenesis, liver damage	Apple and apple products
Ochratoxin	*Aspergillus ochraceus*, *A. carbonarius*, *Penicillium verrucosum*	Endemic nephropathy, carcinogenesis	Grains, peanuts, grapes, green coffee
Citrinin	*Aspergillus, Penicillium*	Nephrotoxicity	Cereal grains
Penitrem(s)		Tremors, incoordination, bloody diarrhea, death	Moldy cream cheese, English walnuts, hamburger bun, beer
Ergot alkaloids	*Claviceps purpurea*	Ergotism	Grains

Aflatoxins Among the various mycotoxins, the aflatoxins (Fig. 27-21) have been the subject of the most intensive research because of the potent hepatocarcinogenicity and toxicity of aflatoxin B1 in rats. Epidemiological studies conducted in Africa and Asia suggest that it is a human hepatocarcinogen, and various other reports have implicated the aflatoxins in incidences of human toxicity. Aflatoxin B1 is the most potent natural carcinogen known and is the major aflatoxin produced by toxigenic strains (Bennett and Klich, 2003). Generally, aflatoxins occur in susceptible crops as mixtures of aflatoxins B1, B2, G1, and G2, with only aflatoxins B1 and G1 demonstrating carcinogenicity. A carcinogenic hydroxylated metabolite

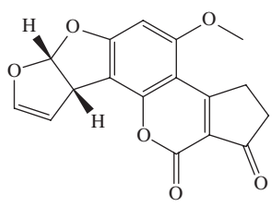

Figure 27-21. *Aflatoxin B1.*

of aflatoxin B1 (termed aflatoxin M1) can occur in the milk from dairy cows that consume contaminated feed. Aflatoxins may occur in a number of susceptible commodities and products derived from them, including edible nuts (peanuts, pistachios, almonds, walnuts, pecans, and Brazil nuts), oil seeds (cottonseed and copra), and grains (corn, grain sorghum, and millet). In tropical regions, aflatoxin can be produced in unrefrigerated prepared foods. The two major sources of aflatoxin contamination of commodities are field contamination, especially during times of drought and other stresses, which allow insect damage that opens the plant to mold attack, and inadequate storage conditions. Aflatoxin B1 is acutely toxic in all species studied, with an LD50 ranging from 0.5 mg/kg for the duckling to 60 mg/kg for the mouse. Death typically results from hepatotoxicity. Aflatoxin B1 is also highly mutagenic, hepatocarcinogenic, and possibly teratogenic. There exists a wide range of species-susceptibility to aflatoxin B1. For instance, aflatoxin B1 appears to be the most hepatocarcinogenic compound known for the rat, but the adult mouse is essentially totally resistant to its hepatocarcinogenicity (Kotsonis and Burdoch, 2013). Such species differences may be due in part to differences in biotransformation (glutathione conjugation) and susceptibility to the initial biochemical lesion (Monroe and Eaton, 1987). Progress has been made in decreasing the level of aflatoxins in specific commodities in developed countries, such as ensuring adequate storage conditions, careful monitoring of susceptible commodities for aflatoxin, and the banning of lots that exceed the action level for aflatoxin B1. The hepatocarcinogenicity of aflatoxin B_1 is associated with the formation of covalent adducts with DNA, RNA, and protein. Damage to DNA is thought to be the initial biochemical lesion.

Trichothecenes The trichothecenes (Fig. 27-22) constitute more than 60 sesquiterpenoid metabolites produced by a number of fungal genera including *Fusarium, Myrothecium*, *Phomopsis, Stachybotrys*, *Trichoderma*, *Trichothecium*, and others. They are commonly found as food and feed contaminants, and consumption of these mycotoxins can result in alimentary hemorrhage and vomiting; direct contact causes dermatitis (Bennett and Klich, 2003). *Fusarium* head blight, caused by trichothecene-producing *Fusarium* species, is a destructive disease of cereal grain crops that has a worldwide economic impact. Consumption of contaminated grain has been associated with intestinal irritation in mammals and can lead to feed refusal in livestock and other toxic responses (Eriksen and Pettersson, 2004). There have been many reported cases of trichothecene toxicity in farm animals and a few in humans. Alimentary toxic aleukia (ATA) is a frequently fatal mycotoxicosis, caused by the ingestion of contaminated overwintered grain or grain by-products. ATA can be caused by trichothecene toxins (e.g., T-2 toxin) in humans and is characterized by leukopenia, agranulocytosis, necrotic angina, a hemorrhagic rash, sepsis, exhaustion of the bone marrow, bleeding from the nose, throat, and gums, and fever. One major outbreak was reported in Russia during 1944 around Orenburg, Siberia. About 10% of the population was affected and mortality rates in the affected population were as high as 60% in some counties. The symptoms of ATA could be induced in cats by administration of the toxins, but not in other experimental models (Bennett and Klich, 2003; Kotsonis and Burdoch, 2013). Trichothecenes bind to ribosomes and inhibit protein synthesis. The acute LD50s of the trichothecenes range from 0.5 to 70 mg/kg. The extent of toxicity associated with the trichothecenes in humans and farm animals is poorly understood, owing in part to the number of entities in this group and the difficulty of assaying for these compounds (JECFA, 2001).

Fumonisins Fumonisins are produced by a number of *Fusarium* species, notably *Fusarium verticillioides* (formerly *F. moniliforme*), *F. proliferatum,* and *F. nygamai.* The major species of economic importance is *F. verticillioides* because it grows in corn, in both vegetative and reproductive tissues. *F. verticillioides* is present in virtually all corn samples (Marasas et al., 2001). Most strains do not produce the toxin, so the presence of the fungus does not necessarily mean that fumonisin is also present (Plumlee and Galey, 1994). The most abundantly produced member of the family is fumonisin B1. Fumonisins affect animals in different ways by interfering with sphingolipid metabolism. They cause leukoencephalomalacia (hole in the head syndrome) in equines and rabbits; pulmonary edema and hydrothorax in swine; and hepatotoxic and hepatocarcinogenic effects, and apoptosis in the liver of rats (Bennett and Klich, 2003). In humans, there is a probable link with esophageal cancer. The occurrence of fumonisin B1 is correlated with the occurrence of a higher incidence of esophageal cancer in regions of Transkei (South Africa), China, and northeast Italy (Peraica et al., 1999). A possible case of acute exposure to fumonisin B1 involved 27 villages in India, where consumption of unleavened bread made from moldy sorghum or corn caused transient abdominal pain, borborygmus, and diarrhea. All those affected recovered fully (Bhat et al., 1997). Fumonisins can cause neural tube defects in experimental animals and thus may also have a role in human cases. The International Agency for Research on Cancer has evaluated the cancer risk of fumonisins to humans and classified them as group 2B (possibly carcinogenic to humans, that is, there is *inadequate evidence* of carcinogenicity in humans, but *sufficient evidence* of carcinogenicity in animals) (IARC, 2002). Fumonisins target different organs in various species, but the underlying mechanism is a disruption of lipid metabolism by inhibition of ceramide synthetase, an enzyme integral to the formation of complex lipids for use in membranes (ICSP, 2000; IARC, 2002).

Ochratoxin A Ochratoxin A (Fig. 27-23) is primarily produced by *Aspergillus ochraceus*, *A. carbonarius*, and *Penicillium verrucosum*. Human exposure occurs through the consumption of contaminated small grains (barley, wheat, and corn), coffee beans,

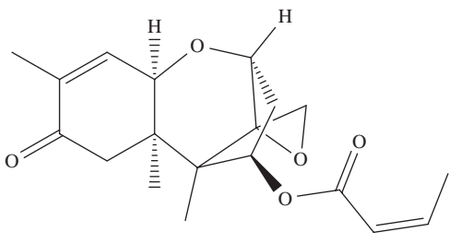

Figure 27-22. *Trichothecene.*

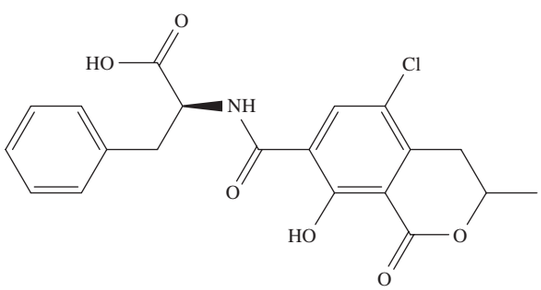

Figure 27-23. *Ochratoxin A.*

and grapes. Ochratoxin A is a nephrotoxin to all animal species studied. It binds tightly to albumin in the blood and can therefore have a very long serum half-life. Of all the ochratoxins studied, ochratoxin A has the longest half-life in humans for elimination (Creppy, 1999). Animal studies indicate that in addition to being a nephrotoxin, ochratoxin A is also a liver toxin, an immune suppressant, a potent teratogen, and a carcinogen (Bennett and Klich, 2003). An important molecular mechanism of action of ochratoxin A is the inhibition of the enzymes involved in phenylalanine metabolism including phenylalanine-tRNA synthetase. In addition, ochratoxin A inhibits mitochondrial ATP production and also stimulates lipid peroxidation (Marquardt and Frohlich, 1992). Initial epidemiological evidence determined that there is an association between exposures to ochratoxin A and the development of Balkan endemic nephropathy (BEN) and renal tumors in parts of eastern Europe. However, recent evidence strongly suggests that the causative agent is aristolochic acid, and not ochratoxin A (Pavlović, 2013).

Ergot Alkaloids Ergot poisoning (ergotism) in humans and domestic animals is one of the oldest known diseases caused by ergot alkaloids. They are produced by the fungus *Claviceps purpurea* and other genera of Claviceps that infect rye and cereals. Ergot alkaloids cause vasoconstriction and reduced blood flow by direct action on the smooth muscles of the arterioles and uterus; the most affected regions being the lower extremities (lower extremity ischemia). The disruption of blood flow causes gangrene, loss of hands and feet, as well as miscarriage of fetuses. Ergot alkaloids also stimulate the central nervous system, resulting in strange hallucinations, itchy and burning skin (Belser-Ehrlich et al., 2013).

Bovine Spongiform Encephalopathy

BSE is a form of transmissible spongiform encephalopathies (TSEs), which are a group of neurodegenerative disorders. In humans, the diseases kuru and Creutzfeldt–Jakob Disease (CJD) are TSEs. The causative agents for TSEs are prions. Normal prion is a cellular protein, designated PrP^{c} and is found on the surface of neurons. The general term for pathogenic (infectious) isoforms of PrP^{c} is PrP^{res} (because they are proteinase K-resistant). The PrP^{res} acts as a template and replicates by converting normal cellular proteins into copies of itself. Other names for PrP^{res} are PrP^{Sc} or PrP^{TSE}. The infective agent can be transferred using preparations of neural tissue from infected animals *across species barriers*. Horizontal transmission from mother to offspring and lateral transmission through biting or injury has been reported. The protein is resistant to heat, antimicrobials, ultraviolet or ionizing radiation, and is not consistently inactivated with alcohol, formaldehyde, glutaraldehyde, or sodium hydroxide. Phenol and sodium hypochlorite disinfection have had variable success.

Clinically, these diseases present neurological deterioration and wasting. The incubation period and interval from clinical onset to inexorable death are determined by the dose of the infective agent, its virulence, and the genetic makeup of the victim. The incubation of BSE in cattle is generally four to five years (range of 20 months to 18 years) and an interval of 1 to 12 months from the presentation of clinical signs to death. Characteristic histological lesions in the brain and spinal cord are vacuolation and "spongiform" changes. BSE fibrils (long strands of the prion protein) in spinal cord preparations may be seen with electron microscopy (Flechsig and Weissmann, 2004). As a response to the concerns about transmission, new enhanced BSE-related feed bans went into effect in Canada in 2007 and in the United States in 2009. The enhanced bans prohibit most proteins, which include potentially BSE infectious tissues from all animal feeds, pet foods, and fertilizers not just from cattle feed as required by bans instituted in 1997 (Kotsonis and Burdoch, 2013).

Some Toxicants Generated in Food During Cooking or Processing

Polycyclic Aromatic Hydrocarbons Polycyclic aromatic hydrocarbons (PAHs) are largely formed when food is cooked using high-temperature methods, such as frying, roasting, barbecuing, grilling, and smoking directly over an open flame. Grilling food, particularly meat, over log fire in which the food is in direct contact with the flame is expected to produce high levels of PAHs. Fat and juices from meat being grilled directly over an open fire drip onto the fire, causing flames. These flames contain PAHs that then adhere to the surface of the meat; hence, charring of meat produces significant amounts of PAHs. PAHs can also be formed during smoking of meats (Cross and Sinha, 2004). Tobacco smoke contains high concentrations of PAHs as well. Therefore, burning of the organic matter in food produces PAHs. One of the widely studied food-associated PAHs is benzo[*a*]pyrene (B[*a*]P) (Fig. 27-24). Studies on PAHs in animals have shown various toxicological effects, such as hematotoxicity, reproductive and developmental toxicity, immunotoxicity, and carcinogenicity. B[*a*]P, for example, is classified as a human carcinogen (Group 1). Estimates of PAH intake from food vary widely, ranging from a few nanograms to a few micrograms per person per day (IARC, 2012).

Heterocyclic Amines Heterocyclic amines (HCAs) are generated during cooking, particularly meat and fish by pan frying or grilling. There are more than 20 HCAs. They are formed when amino acids, sugars, and creatine react at high temperatures. In other words, HCAs are formed as a result of high-temperature cooking of proteins and carbohydrates. Meats cooked at high temperatures (e.g., above 300ºF), as well as well-done meat that are cooked for a long time tend to form more HCAs. Like PAHs, HCAs are also metabolized to bioactivated genotoxic carcinogens that form DNA adducts. HCAs are rapidly absorbed by the GI tract, distributed to all organs, and decline to undetectable levels within 72 hours (Kotsonis and Burdoch, 2013). There are different types of HCAs in cooked foods. The amount of MeIQx (2-amino-3,8-dimethylimidazo[4,5-f]quinoxaline) (Fig. 27-25) formed during cooking seems to be

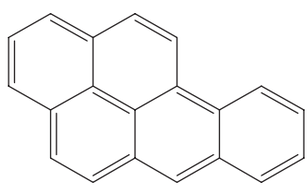

Figure 27-24. *Benzo[a]pyrene.*

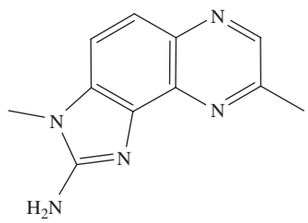

Figure 27-25. *MeIQx.*

higher than any other HCAs formed, being 3.10 ng/g in food-grade beef extract, 2.33 ng/g in broiled chicken, and 2.11 ng/g in broiled beef (Kotsonis and Burdoch, 2013). HCAs are indirect carcinogens because they need to be metabolically activated into electrophilic carcinogen that form DNA adducts. Unreacted HCAs are subject to phase II detoxication reactions and are excreted via the urine and feces.

N-Nitroso Compounds *N*-nitroso compounds (NOCs) are so named because they contain an *N*-nitroso group. Several hundred *N*-nitroso compounds are currently known. There are two major classes of NOCs: nitrosamines and nitrosamides. Nitrosamines are more stable than nitrosamides. Nitrosamines are metabolically activated by hydroxylation, and through a series of steps ultimately form a carbonium ion that alkylates DNA. Nitrosamides spontaneously decompose to a carbonium ion at physiological pH by a similar mechanism. Nitrosamides are potent neurocarcinogens in animal models. Diet is a major source of NOCs, but endogenous NOC formation is estimated to account for 45% to 75% of total exposure to NOCs. Nitrites, amines, and amides found in processed meat are the precursors for the endogenous formation of NOCs in the stomach. In addition, nitrosamines are also found in nitrite-preserved foods, such as meat and fish. NOCs may also be formed endogenously after consumption of nitrate, which is reduced to nitrite by bacteria in the gut. The main sources of dietary nitrate are grain products and many leafy vegetables. The NOCs in food could be volatile or nonvolatile. Volatile NOCs, such as *N*-nitrosodimethylamine (NDMA; Fig. 27-26), *N*-nitrosodiethylamine (NDEA), *N*-nitrosopyrrolidine (NPYR; Fig. 27-27), and *N*-nitrosopiperidine (NPIP) are known to be carcinogenic, whereas the non-volatile NOCs, such as *N*-nitrosoproline (NPRO) are not known to be mutagenic or carcinogenic. NDMA and NPYR have been commonly reported in food. NOCs originate from two sources: environmental formation and endogenous formation. Environmental sources have declined over the last several years but still include foods (e.g., nitrate-cured meats) and beverages (e.g., malt beverages), occupational exposure, and rubber products. NOCs formed in vivo may actually constitute the greatest exposure and are formed from nitrosation of amines and amides in several areas, including the stomach, where the most favorable conditions exist (pH 2 to 4), although consumption of Histamine H2-receptor blockers or antacids decreases the formation of NOCs (Kotsonis and Burdoch, 2013). In the western countries, the consumption of volatile NOCs is usually 0.3 to 1.0 μg/person/day, whereas that of non-volatile NOCs is usually 10 to 100 μg/person/day. In Asia, the exposure to volatile NOCs is significantly higher because of the consumption of dried and nitrite-salted fish. Cigarette smoke is another significant source of volatile NOCs; an average smoker may be exposed to more than 15 μg volatile NOCs per day (Skog et al., 1998).

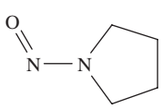

Figure 27-27. *N-nitrosopyrrolidine.*

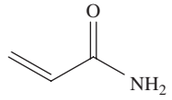

Figure 27-28. *Acrylamide.*

Figure 27-29. *Furan.*

Acrylamide Cooking starchy foods (e.g., potato) at high temperatures (120°C or higher) causes a chemical reaction between certain sugars and the amino acid asparagine present in the food; the reaction forms acrylamide (Fig. 27-28). Longer cooking times and cooking at higher temperatures can increase the amount of acrylamide in foods further. Thus, crunchy, dark brown potato fries are likely to contain higher levels of acrylamide than non-crunchy, non-brown potato fries. Most acrylamide is formed in the final stages of baking, grilling, or frying as the moisture content of the food falls and the surface temperature rises (JECFA, 2005). Acrylamide (the monomer) is known to be a neurotoxin. Repeated dosing of acrylamide in drinking water at 21 mg/kg bw/day for 40 days produces neurotoxicity (JECFA, 2005). Acrylamide was also classified as probably carcinogenic to humans (Group 2A) by IARC (IARC, 1994). Interestingly, the polymer of acrylamide, polyacrylamide, does not have significant toxicity. Acrylamide intake estimates range from 0.3 to 2.0 μg/kg bw/day for the average population. Primary sources include French fries (1% to 30%), potato chips (6% to 46%), coffee (13% to 39%), pastry and cookies (10% to 20%), and bread and rolls/toasts (10% to 30%). The NOEL for morphological change in nerves and for reproductive effects is 200 and 2000 μg/kg bw/day, respectively (JECFA, 2005). Table 27-12 shows the acrylamide content of some common food.

Furan Furan (Fig. 27-29) occurs in a number of foods that undergo heat treatment, such as canned and jarred foods, including baby food. It is considered by IARC (1995) to be possibly carcinogenic to humans. Furan is hepatotoxic and shows clear evidence of carcinogenicity in both sexes in mice and rats (NTP, 1993). Furan is produced in a variety of experimental systems, including heating of sugars (e.g., glucose, lactose, fructose, xylose, rhamnose), heating sugars in the presence of amino acids or protein (e.g., alanine, cysteine, casein), and thermal degradation of vitamins (ascorbic acid, dehydroascorbic acid, thiamine) (FDA, 2004). Furan has been found in a small number of heat-treated foods, including coffee, canned meat, baked bread, cooked chicken, sodium caseinate, hazelnuts, soy protein isolate, hydrolyzed soy protein, rapeseed protein, fish protein concentrate, and caramel (FDA, 2004). Very little information has been developed on furan levels in food.

Some Heavy Metal Contaminants in Food

There are no standard definitions of heavy metals. The term is frequently used to indicate toxic metals with a specific gravity of 5 or above. The heavy metals discussed here are lead, cadmium, mercury, and arsenic. Elsewhere in the book (Chap. 23), these heavy

Table 27-12

Representative Concentrations of Acrylamide in Several Foods

FOOD	MEAN CONC. (μg/kg)	REPORTED MAXIMUM (μg/kg)

metals are discussed along with the history of their human exposure, target organ toxicity, as well as the mechanisms of toxicity. Those are not repeated here.

Lead Lead is a toxic metal present in our environment in small amounts. Everyone is exposed to lead from daily actions such as inhaling dust, eating food, or drinking water. Lead poisoning in children is a potential cause for concern. FDA's provisional total tolerable intake level (PTTIL) for lead by small children is 6 μg/day (FDA, 2006c). FDA also recommends that the lead levels in candy products likely to be consumed frequently by small children do not exceed 0.1 ppm (FDA, 2006c). This recommended maximum level is consistent with the FDA's long-standing goal of reducing lead levels in the food supply.

Cadmium Cadmium is widely dispersed into the environment by industrial and man-made activities. Cadmium released into the environment can be associated with respirable-sized airborne particles and can be carried long distances. It is ultimately deposited onto the Earth by rain or falling out of the air. Once on the ground, cadmium moves easily through soil layers and is taken up into the food chain by uptake into plants such as leafy vegetables, root crops, cereals, and grains (e.g., rice and wheat). Cadmium is primarily toxic to the proximal tubular cells of the kidney and tends to accumulate in the cortex of the kidney, eventually leading to renal failure. Bone demineralization occurs with prolonged exposure. Cadmium absorption in humans is the greatest with pulmonary exposure, but it is relatively low (3% to 5%) after dietary exposure (EFSA, 2009c). Because cadmium has a very long half-life in the body (10 to 30 years), cadmium exposure is still a cause for concern. JECFA (2005) investigated cadmium consumption for several countries including the United States and found that the current total intake of cadmium is 40% to 60% of the Provisional Tolerable Weekly Intake (PTWI) of 7 μg/kg bw/week established several years ago (JECFA, 2005). Many U.S. health agencies have set exposure standards designed to protect the general public from excess cadmium exposure from various sources, such as a maximum limit of 5 μg/L (5 ppb) in drinking water (see ATSDR, 2008).

Mercury Currently, exposure to elemental mercury is relatively rare. Of interest to food toxicology is methylmercury, which is formed in aquatic environments by bacterial action on elemental mercury. Anthropogenic sources that can add elemental mercury to aquatic environments include burning of coal (which contains mercury), chloralkali processes, and other sources of elemental mercury discharge into aquatic environments. Methylmercury is neurotoxic. Developmental delays have been documented in children borne of mothers exposed to methylmercury (Carrington and Bolger, 1992). Methylmercury becomes concentrated in fish including bonito (*Sarda* spp.), halibut (*Hippoglossus* spp.), mackerel (*Scomberomorus* spp.), marlin (*Makaira* spp.), shark (all species), swordfish (*Xiphias* gladius), and bluefin tuna (*Thunnus* spp.). Human exposure to mercury can occur through the consumption of these fish species. The current FDA action level is 1.0 ppm mercury in the edible portion of fish (FDA, 2011b).

Arsenic Arsenic is a naturally occurring element widely distributed in the air, water, and land. In the environment, arsenic may exist as inorganic and organic arsenic compounds. Inorganic arsenic compounds are highly toxic. For most people, food is the largest source of arsenic exposure, although much of this is likely to be in the organic form, which is less toxic. The highest levels of total arsenic (inorganic plus organic) in foods can be found in seafood, rice, rice cereal and other rice products, mushrooms, poultry, and other foods. Rice is of particular concern because it is a major part of the diet in many parts of the world. It is also a major component of many of the cereals consumed by infants and young children. In the United States, an average adult intake of dietary inorganic arsenic was estimated to be 3.2 μg/day, with a range of 1 to 20 μg/day (Hughes et al., 2011). EFSA (2014) reported a mean dietary exposure among European infants, toddlers, and other children ranging from 0.20 to 1.37 μg/kg bw/day, whereas the mean dietary exposure among the adult population ranged from 0.09 to 0.38 μg/kg bw/day. FDA proposed an "action level" of 10 μg/kg (10 ppb) for inorganic arsenic in apple juice. This is the same level set by the United States (EPA) for arsenic in drinking water (FDA, 2013).

FOOD ALLERGY

Definition

In 2003 the World Allergy Organization of the World Health Organization (WHO) proposed that adverse nontoxic reactions to food in general should be termed *food hypersensitivity*. If there is no role of the immune system in the development of food hypersensitivity, it should be called *non-allergic food hypersensitivity* (e.g., lactose intolerance, hypersensitivity toward sulfites). If an immunologic mechanism has been demonstrated, the appropriate term is *food allergy*. Food allergy could further be subdivided into *IgE-mediated food allergy* (e.g., allergy caused by milk, egg, peanut, etc.) and *non-IgE-mediated food allergy* (e.g., celiac disease) (Johansson et al., 2004). The IgE-mediated food allergy involves

the humoral immune response (antibody-mediated), whereas the non-IgE-mediated food allergy involves the cell-mediated immune response.

Occurrence and Symptoms

Food allergies are abnormal responses of the immune system to certain food components (allergens) in some individuals. The vast majority of consumers may not react to the same allergen. *The allergens in foods are typically naturally occurring proteins*. Basically, any food that contains protein has the potential to elicit allergic sensitization in some individuals. There are both genetic and environmental risk factors determining food allergy. Genetic risk factors include a family history of atopic disorders. Environmental factors include the extent and duration of exposure to the allergen from the environment, route of exposure, prior exposure to similar antigens (determining cross-reactivity), and others. The evidence of environmental factors modulating the expression of food allergy is provided by increasing peanut allergy in children (Sicherer et al., 2003; Benedé et al., 2016). Recent findings suggest that in the dual environmental exposure, the scenario of food allergy and the exposure through skin promote sensitization, while early exposure through the GI tract may be tolerogenic. This is supported by clinical findings that early consumption of food, such as peanuts, fish, or wheat is associated with a lower incidence of food allergy (Benedé et al., 2016). The relationship between diet during infancy (other than the allergenic food itself) and the development of allergic diseases is not well understood. Exposure to an increased diversity of foods in early life is inversely associated with allergic diseases including food allergy (Roduit et al., 2014; Benedé et al., 2016). But there are relatively few studies identifying specific dietary components that might be a risk for the development of food allergy (Benedé et al., 2016).

Approximately 6% of young children and 3.7% of adults in the United States have a food allergy. In young children the most common food allergies are those to cow's milk (2.5%), egg (1.3%), peanut (0.8%), wheat (about 0.4%), soy (about 0.4%), tree nuts (0.2%), fish (0.1%), and shellfish (0.1%). Early childhood allergies to milk, egg, soy, and wheat usually resolve by school age (about 80%). Although peanut, tree nut, and seafood allergies are generally considered permanent, about 20% of young children with peanut allergy experience resolution by 5 years of age (although recurrence is also possible). Adults are more likely to have allergies to shellfish (2%), peanut (0.6%), tree nuts (0.5%), and fish (0.4%). Reactions to fruits and vegetables are common (approximately 5%) but usually not severe. Allergy to seeds (e.g., sesame) is being increasingly reported. To summarize, egg and milk allergies are the most common food allergies among infants but are often outgrown. Shellfish allergy is more common among adults than children, while peanut allergy is equally common among children and adults (Sicherer and Sampson, 2006).

The symptoms of food allergies may range from mild discomfort to severe, life-threatening reactions that require immediate medical attention. Symptoms may involve itching, redness, swelling in the skin; itching and swelling of the eyes; swelling of oral cavity; pain in the GI tract; nausea, vomiting, diarrhea; itching and swelling of the nose and throat; asthma; chest pain, abnormal heart rhythm, and very low blood pressure causing fainting. Allergic reactions to foods generally occur within a few minutes to one hour (immediate hypersensitivity) after eating the offending food. Symptoms can last for days or even weeks. The specific symptoms and severity of an allergic reaction are affected by the amount of the allergen consumed and by the sensitivity of the allergic person (WHO-INFOSAN, 2006).

Eosinophilic esophagitis (EoE) is a newly recognized chronic disease that can be associated with food allergies. It affects as many as 56 of every 100,000 people in the United States, and is characterized by inflammation and accumulation of eosinophils in the esophagus. Symptoms include nausea, vomiting, and abdominal pain after eating and can resemble acid reflux. Recently, Davis et al. (2016) identified that calpain 14 is the causative agent of EoE. Calpain 14 is an IL-13-induced protease that mediates esophageal epithelial barrier impairment. EoE involves T-helper type 2 (Th2) response in esophageal mucosal epithelium.

Foods That Elicit Allergic Reactions

Overall, more than 170 foods have been documented as causing food allergies (Hefle et al., 1996). The eight most common foods that elicit allergic reactions are eggs, milk, fish, crustacean shellfish (e.g., crab, lobster, and shrimp), tree nuts (e.g., almonds, walnuts, and pecans), peanuts, wheat, and soybeans, although reactions to many other foods can occur as well. Food-induced anaphylactic reactions are possible, but the more prevalent adverse immunological reactions include eczema, urticaria, angioedema, nausea, vomiting, diarrhea, rhinoconjunctivitis, and asthma (Kotsonis and Burdoch, 2013).

Mechanism of IgE and Non-IgE-Mediated Food Allergic Reactions

IgE-mediated reactions are true allergic responses; these are also known as type I hypersensitivity responses that typically affect the cutaneous, respiratory, GI and/or cardiovascular systems. IgEs are produced by B cells, and the response usually occurs within an hour of exposure and can result in anaphylaxis. Most allergens, including food allergens, are proteins. In IgE-mediated allergic reaction, the allergenic proteins are taken up by the antigen presenting cells (APCs), such as the dendritic cells. The APCs cleave the proteins into pieces in the lysosomes; these pieces are presented at the cell surface in complex with MHC class II molecules. The MHC–antigen (allergen) complex is recognized by the $CD4^+$ T-helper (Th) cells, which then differentiate into T-helper type 2 (Th2) effector cells in individuals who have genetic predisposition to the allergen (atopic individuals). Th2 cells produce a whole array of cytokines of which IL-4 and IL-13 are critical for the synthesis of IgE by B cells. During an allergic response, IgEs bind to the IgE receptors (FcεRI and FcεRII) on mast cells (in tissues) and basophils (in circulation). When two or more IgEs bound to receptors on the mast cells or basophils are cross-linked by the allergen through the allergenic epitope, these cells are activated. Both mast cells and basophils contain special cytoplasmic granules that store many mediators of inflammation (i.e., histamine, tryptase, cysteinyl leukotrienes, prostaglandin D2). The extracellular release of these mediators following activation of these cells is known as degranulation. The released mediators of inflammation trigger allergic response and allergy symptoms. Some examples of IgE-mediated food allergy symptoms include urticaria (hives), eczema, dermatitis, pruritas (severe itching of the skin), rash, nausea, vomiting, diarrhea, abdominal cramps, asthma, wheezing, rhinitis, bronchospasm, anaphylactic shock, hypotension, palatal itching, swelling including tongue and larynx, and methemoglobinemia. The most severe manifestation of food allergy is anaphylaxis, which is an acute reaction that affects two or more organ systems and can be life-threatening (Wang and Sampson, 2009; Benedé et al., 2016).

Non-IgE-mediated food allergy is less frequent and it occurs in the absence of detectable food-specific IgE antibodies in the serum or skin. The mechanisms of non-IgE-mediated food allergy are not well understood, but are thought to be cell-mediated. They occur at least 2 hours after exposure (or later) and mostly involve acute or chronic inflammation in the GI tract. The delayed onset of symptoms makes the clinical association between offending food and the clinical symptoms difficult. The non-IgE-mediated allergies can be classified into different types of hypersensitivity responses, such as Type II (IgG- or IgM-mediated cytotoxic hypersensitivity response), Type III (immune complex–mediated hypersensitivity response), and Type IV (cell-mediated hypersensitivity response). Both Type II and III responses involve activation of the complement proteins. The gut mucosal immune system develops tolerance to macronutrients that could be potentially immunogenic (e.g., proteins). This immune tolerance is maintained by actively suppressing the antigen-specific regulatory T (Treg) cells. In the first few years of life, humans gradually develop an intricate balance between tolerance and immune reactivity in the gut mucosa along with a tremendous expansion of gut-associated lymphoid tissue (GALT). Expectedly, both IgE- and non-IgE-mediated food allergy is frequently seen during this period. Non-IgE-mediated food reactions are classified as negative skin test results or specific IgE to foods, with positive challenge to the offending food. The reactions can vary by system, from GI to cutaneous to respiratory; GI reactions are the most common reactions. Some examples of non-IgE-mediated food allergy symptoms include atopic dermatitis (could be mixed IgE/non-IgE), dermatitis herpetiformis, food protein–induced enterocolitis syndrome, food protein–induced proctitis, eosinophilic esophagitis (could be mixed IgE/non-IgE), celiac disease, and pulmonary hemosiderosis (Heiner syndrome) (Spergel, 2006; Jyonouchi, 2008).

Diagnosis and Treatment of Food Allergy

The first step in diagnosing a food allergy is to obtain/develop a detailed medical history. The next step is to conduct certain tests in order to identify food allergy. The tests that an allergy specialist may conduct are: (1) Skin prick test; (2) Blood test; (3) Oral food challenge; (4) Elimination diet.

The skin prick test (SPT) is conducted by placing a drop of solution (or mashed fresh material, such as fruits or vegetables) containing the food allergen on the forearm or back of the person. Then the area of the skin where the material has been applied is gently pricked to let the applied material enter just below the surface. A positive reaction is indicated by a wheal (a raised bump surrounded by a small circle of itchy red skin) within 30 minutes or so. A positive SPT may prompt further tests by the physician. *Blood test* measures the presence of IgE antibodies to specific food. In the past, the test was called RAST (radioallergosorbent assay). The assay used radiolabeled secondary antibodies that bind and detect human IgE against the food allergen. Modern tests do not use any radioactivity. The RAST has been replaced by more sensitive fluorescence enzyme-labeled immunoassays. As opposed to SPT which is rapid, the blood test takes a few days to perform; however, performing SPT on a person whose skin is full of rashes is impossible; hence, the blood test becomes important for such patients. If the SPT and blood test are not sufficient for the physician to arrive at a conclusion, an *oral food challenge (OFC)* may be required; OFC is a highly accurate diagnostic test for food allergy. Because OFC has the potential to cause a serious reaction, it should be performed under the advice and supervision of a qualified allergy specialist doctor. Briefly, the person is fed the suspected offending food in small, incremental doses until a reaction is observed. The food challenge is then stopped. Depending on the severity of the reactions, the person may be given antihistamine to relieve the symptoms. Opposite to the OFC is the *elimination diet* trial. In this method, the person is advised to avoid the suspected offending food(s) for about a month. The disappearance of symptoms is monitored, and the offending food is identified. Once the offending food is identified by the elimination diet trial, the physician may want to conduct an OFC with the same food to double-confirm the role of the food in precipitating the food allergy (Sicherer and Sampson, 2006).

The best remedy for food allergies is to avoid the foods that cause the allergy. In reality, this may be difficult to practice because the possibility of inadvertent exposure to the offending allergens from the surrounding environment cannot be ruled out. In general, antihistamines should work for mild reactions and epinephrine for serious reactions. However, a person who is suffering from confirmed or suspected food allergy should always consult the doctor about the necessary steps he/she should take, and follow the doctor's advice. The reader may visit the University of Nebraska "Treatment of food allergies" page of the Food Allergy Research and Resource Program for a collection of resources on this topic (http://farrp.unl.edu/resources/gi-fas/treatment-of-food-allergies). In this respect, the FALCPA labeling (discussed above) is an important tool to alert consumers regarding the presence of potential allergic ingredients in the food.

EXAMPLES OF INADVERTENT FOOD CONTAMINATIONS

There have been only a few incidents of mass poisonings *via* food, two of which involved cooking oil contaminated with polychlorinated organics. The first became known as yusho, or rice oil disease, from rice oil contamination originally thought to be confined to polychlorinated biphenyls (PCBs), but has since been revised to include polychlorinated quarterphenyls and polychlorinated dibenzofurans (PCDFs). The poisoning occurred in 1968 in Japan and affected approximately 2000 individuals. The most vulnerable were newborns of poisoned mothers. The liver and skin were the most severely affected. Symptoms included dark brown pigmentation of nails; acne-like eruptions; increased eye discharge; visual disturbances; pigmentation of the skin, lips, and gingiva; swelling of the upper eyelids; hyperemia of the conjunctiva; enlargement and elevation of hair follicles; itching; increased sweating of the palms; hyperkeratotic plaques on the soles and palms; and generalized malaise (Kanagawa et al., 2008; Kotsonis and Burdoch, 2013).

Both polybrominated biphenyls (PBBs) (sold as fire retardant under the trade name FireMaster) and magnesium oxide (sold as a cattle feed supplement under the trade name NutriMaster) were produced at the same site in Michigan. In early 1973, FireMaster was placed in bags labeled NutriMaster because of a mix-up, and several farms received animal feed contaminated by FireMaster. By the time the problem was detected in early 1974, approximately 650 lbs of PBBs had entered the food chain through milk and other dairy products, beef products, and contaminated swine, sheep, chickens, and eggs. Over 500 Michigan farms were quarantined, and approximately 30,000 cattle, 4500 swine, 1500 sheep, and 1.5 million chickens were destroyed, along with over 800 tons of animal feed, 18,000 pounds of cheese, 2500 pounds of butter, 5 million eggs, and 34,000 pounds of dried milk products. PBB-exposed Michigan residents had a variety of complaints including nausea, abdominal pain, loss of appetite, joint pain, fatigue, and weakness, and although a cause–effect relationship could not be established

for these symptoms, there is a fairly strong case for development of chloracne from exposure to PBBs (MDCH, 2011; Kotsonis and Burdoch, 2013).

CONCLUSION

Food toxicology is a unique discipline, in the sense that the words "food" and "toxicology" are apparently not compatible to each other. People take it for granted that food is always nutritious and hedonic or of satiatal value. It should be clear from the preceding discussion that many foods that have been consumed for hundreds of years by humans may naturally contain antinutrients/toxicants that, if consumed in large amounts, could cause health concerns. Microbial food contamination is another problem. There is also the issue of food allergy among a seemingly increasing fraction of the population. The FD&C Act provides some thoughtful and pragmatic solutions through the creative use of specifications, process and manufacturing controls, action levels, tolerances, warning labels, advisories, and outright prohibitions (Kotsonis and Burdoch, 2013).

BIOLOGY OF EATING AND DIGESTION

All biotic organisms derive energy from food to sustain life and this energy "drives" various cellular functions, including digestion, metabolism, pumping blood, and muscle contractions. Nutrients can broadly be defined as chemical substances (typically found in foods or supplements) that are necessary for proper growth and development, reproduction, cellular function and maintenance, and repair following injury. Based on their chemical nature, nutrients can be grouped into organic (carbon-containing) and inorganic classifications. Carbohydrates, proteins, fats, and vitamins comprise the former, while minerals and water are inorganic nutrients essential for life (Stipanuk, 2006). Inorganic nutrients such as minerals can be absorbed into the body through food and are generally incorporated into the food chain through environmental sources (soil, water). Minerals comprise about 4% of the body weight in humans and in combination with water furnish a major part of the obligatory milieu necessary for cellular functioning (pH, osmolarity). Macrominerals are those whose abundance is generally 0.01% of body weight or daily required amounts exceed 100 mg/day. Calcium, phosphorous, sodium, and magnesium fall in this group. Other minerals that are not as abundant can be equally important for an organism. Trace minerals are defined as minerals whose concentration is less than 0.01% of total body weight. Other alternative definitions include nutrients whose requirements are below 1 ppm. Iron, zinc, copper, iodine, selenium, and molybdenum are six essential trace elements with established recommended dietary allowances. Overall, trace nutrients perform a variety of important functions, including transport of oxygen (iron as a part of hemoglobin), catalysis of biological reactions as component of enzymes (iron, zinc), and as part of other organic molecules (selenocysteine). While inorganic compounds serve important roles in physiology, the energy in food is derived from metabolism of organic substances. Organic compounds are generally synthesized by living cells from simpler molecules. For example, green plants and marine phytoplankton utilize photosynthesis to convert the very simple molecule carbon dioxide into more complex, energy-rich compounds such as carbohydrates using the energy from the sunlight. Because most bacteria and higher organisms cannot carry out photosynthesis, they derive their energy by metabolism of preformed organic molecules, such as carbohydrates. In general, bacteria utilize simpler organic molecules and animals and humans require more complex macronutrients (proteins, fats, and carbohydrates) to meet their energy needs.

Digestion of Foods

Common foods are a complex matrix and before the nutrients in food can be utilized they invariably need to undergo digestion. The process of digestion is a remarkable orchestration of many complex biochemical and physiological events, which occurs throughout the gastrointestinal (GI) tract, involving mechanical and chemical breakdown of food into simpler nutrients that are amenable for absorption. The upper GI tract consists of oral cavity, esophagus, and stomach. Breakdown of food begins in the mouth via the actions of enzymes in saliva. Movement of food between sections of the GI tract is restricted via sphincters or valves. In the stomach, food is acted upon by gastric juices, which are secretions from the cardiac, oxyntic, and pyloric glands in the stomach. Gastric juice contains high amounts of hydrochloric acid that is secreted from gastric parietal cells. This along with the enzymes such as pepsin and α-amylase act upon proteins and carbohydrates, respectively, to generate polypeptides and simpler sugars (such as dextrins from starch). Digestion in the small intestine is aided by numerous enzymes supplied by the pancreas, which drains into the proximal portion of the small intestine, the duodenum. Bile is made in the liver and stored in the gall bladder until secreted to aid in the absorption of dietary fats. Pancreatic juice contains digestive enzymes including carboxypeptidases, lipases, amylases, and nucleases. Pancreatic secretions also contain bicarbonate and divalent cations (mostly sodium and potassium) that help neutralize the gastric acid. Almost half of ingested carbohydrates and proteins, and 90% of ingested fat are digested by pancreatic enzymes. In addition to the enzymes, the small intestine itself secretes numerous enzymes including aminopeptidases, lipases, and disaccharidases.

The latter parts of the small intestine, the jejunum and ileum, are primary sites of absorption of nutrients. The surface of the small intestine is uniquely adapted to facilitate the absorption of digested dietary nutrients. The surface area of the intestinal mucosa available for absorption is greatly increased due to a combination of folds called valvulae conniventes (folds of Kerckring) and finger-like projections (villi) that are lined with enterocytes. The luminal surface of the enterocytes is further lined by microvilli that give the mucosal surface brush-border-like appearance. The luminal and basolateral surfaces of the enterocytes are rich in transporters that mediate uptake of nutrients into the enterocytes. Absorption of nutrients into enterocytes may be accomplished by diffusion, facilitated diffusion, or active transport. Luminal digestion of complex carbohydrates involves breakdown via salivary and pancreatic amylases into dextrins that undergo further digestion to simple monosaccharides in the membrane. Furthermore commensal gut microbiota play important roles in breakdown of complex carbohydrates (such as dietary fiber) into substrates that can be utilized by the host. Monosaccharides are transported into the enterocytes by active transport (glucose, galactose) or via facilitated diffusion (fructose). Digestion of proteins begins in the stomach and continues in the lumen of the small intestine. The jejunum is the site of absorption of amino acids and dipeptides and tripeptides. Specific carriers for free amino acid and small peptides in the enterocyte brush border aid absorption. Dietary lipids, such as triacylglycerols, are hydrolyzed by pancreatic and intestinal lipases to free fatty acids or monoacylglycerol. Bile salts along with phospholipids facilitate the absorption of lipids by forming emulsified complexes called micelles, which allows uptake into the enterocyte, where fatty acids are reesterified and packaged into chylomicrons that exit the enterocyte into the lymphatic system. Macronutrient molecules (amino acids, sugars, and fatty acids) that end up in the circulation undergo metabolism in various tissues to be either oxidized to extract energy or stored for future utilization.

Integrated Fuel Metabolism

The requirement for energy to fuel cellular functions in all organisms is continuous. However, food consumption is intermittent. Hence, most organisms have developed processes to store energy from a meal to be utilized until the next meal. Energy in the body is derived from three main nutrient classes: carbohydrates, protein, and fat, which in turn are made up of sugars, amino acids, and free fatty acids, respectively. The principal circulating fuels in the body, glucose and free fatty acids, are stored as glycogen and triglycerides, respectively. Highest concentrations of glycogen are present in the liver and skeletal muscle, it is a macromolecule consisting of branching chains of glucose held together by α-1,4 and 1,6 linkages. Triglycerides are stored in adipose depots in specialized cells (adipocytes) within large lipid droplets. While total body protein constitutes a large percentage of the energy, unlike fats and carbohydrate, protein is not normally utilized as storage form of energy. Proteins are critical in maintaining structure and function and are catabolized for energy only as a last-ditch effort, under extreme conditions. The energetic value of macromolecules per gram of tissue is influenced based on their hydration. While the theoretical energy content of glycogen is approximately 4 kcal/g, due to its highly hydrophilic nature, each gram of glycogen is associated with two to three times its weight of water. Hence, in reality glycogen provides approximately 1 kcal/g of actual energy. This makes storage of energy predominantly in the form of glycogen quite inefficient. In contrast, because triglycerides are stored in a mostly nonaqueous milieu, fat tissue is energy dense, yielding close to the theoretical 9.4 kcal/g of triglyceride. Hence, most animals have developed systems to convert glucose into lipids (lipogenesis) and adipose depots to store de novo synthesized lipids.

The interconversion of fuel sources and release in the time of need is designed to address three priorities of fuel utilization (Shulman et al., 2003). Maintaining a stable supply of substrate for utilization by the brain is the first priority. Because the brain has little to no stored energy in the form of glycogen or triglycerides, it exclusively depends on the liver for maintaining a continuous supply of glucose. Blood glucose concentrations are maintained within a narrow range (55 to 140 mg/dL) via a number of interrelated mechanisms that are highly conserved. Unlike the brain, the heart and to some degree the liver and skeletal muscles derive most of their energy needs through the oxidation of fatty acids. Maintenance of protein reserves and replenishment of proteins (enzymes, cytoskeletal proteins, contractile proteins) following feeding are the next important functions of fuel metabolism. Finally, conversion of existing nutrients into their storage forms (glycogen and triglycerides) is carried via anabolic biological pathways (glycogenesis and lipogenesis).

Hormonal messages generated by the endocrine cells of the pancreas, adipose tissue (adipokines), and GI tract (gut neuropeptides) are critical to orchestrating the multiple processes associated with fuel flux and metabolism. Insulin is the principal hormone required to manage nutrient fuels in both fed and fasted states. The presence and subsequent absorption of food in the GI tract and rise in blood glucose stimulate insulin secretion from the pancreas. Through its actions on various signaling pathways, insulin promotes glucose uptake in peripheral tissues, glycogen synthesis in the liver and muscle, lipid synthesis in adipocytes, and amino acid and protein synthesis in most cells. Insulin also acts to restrain catabolic processes such as lipolysis, gluconeogenesis, and protein degradation, which classically occur under states of low insulin (such as fasting). Following the immediate disposal of absorbed nutrients, the body enters a postabsorptive (early fasting) state, during which the energy derived from glucose supplied directly from the meal is

diminished (Ruderman et al., 2005). In this state, serum levels of insulin start to decrease, and the liver begins metabolic actions to maintain glucose levels by glycogenolysis to release stored glucose and by de novo synthesis of glucose (from gluconeogenic precursors, lactate and fatty acids, and glycerol). Energy for these catabolic and anabolic processes can be derived from metabolism of triglycerides and fatty acids (in adipose tissues). If food remains unavailable for a protracted period, glycogen levels become almost completely depleted in both the muscle and liver, and protein catabolism releases amino acids which become the primary source for glucose production. A rise in glucagon and glucocorticoids (such as cortisol) also characterize this state. These hormones promote lipolysis and breakdown of glycogen.

Set-Point Theory and Neural Control of Energy Balance

A number of redundant feedback mechanisms operate to maintain the homeostasis of energy in living systems. These mechanisms eventually regulate the balance between food intake and energy expenditure to maintain fuel reserves at preset levels. Energy consumed is normally metabolized and utilized to maintain basic metabolic rate and thermogenesis, and carry out cellular processes, organ-specific functions, and movement (muscle contractions). Excess fuels are converted to triglycerides and stored in adipose tissues. Because adipose tissue is the major depot of preserving energy, signals derived from the periphery signal to regions in the brain that coordinate energy balance. When total energy consumed equals the total energy required to meet basal metabolic needs, growth, thermogenesis, and physical activity, the individual is in energy balance, and maintaining this balance will result in relatively stable weight and healthy body composition. When energy intake exceeds the actual energy expenditure, weight gain ensues and body composition can become problematic. The existence of a precise energy balance system is illustrated by considering normal variations in weight among groups of individuals over time. Over the course of a year, the average adult male consumes about 1 million calories, yet body weight of most weight-stable individuals does not fluctuate more than 1 lb. Even a small (about 5%) error in matching intake and expenditure would result in a net change of approximately 6 kg of body weight. Therefore, it is obvious that mechanisms operating within the body can regulate energy balance with exquisite precision.

One theory called the "set-point" theory proposes that food intake and energy expenditure are coordinately regulated by defined regions in the central nervous system that signal to maintain a relatively constant level of energy reserve and body weight (Keesey and Hirvonen, 1997). It is posited that the status of energy stores is sensed by the central nervous system and changes in the afferent signal result in adjustments in food intake and/or energy expenditure. Implicitly, the model requires the existence of four major components of an energy homeostasis system: afferent signals relaying the levels of energy stores, efferent processes regulating energy storage and expenditure, efferent mechanisms controlling ingestive behavior, and integrative centers in the brain to coordinate these processes. Studies have shown that the hypothalamus plays a central role in the control of energy balance, especially food intake. The hormone leptin, secreted in proportion to body fat stores from the adipose tissue, was the first signal to be identified to be a homeostatic regulator of energy balance. Leptin acts on metabolic-sensing neurons in the brain with receptor-mediated actions regulating signaling pathways that in effect decrease food intake (Friedman and Leibel, 1992). Leptin also has potent neurotrophic actions in the brain.

Two populations of neurons are seat of appetite control machinery in the brain, both of which are sensitive to leptin's actions (among other neuropeptides), one expressing orexigenic peptides neuropeptide-Y (NPY) and agouti-related peptide (AGRP) and the other expressing anorexigenic peptides proopiomelanocortin (POMC) and cocaine- and amphetamine-regulated transcript (CART). These are located in the arcuate nucleus of the hypothalamus. Downstream projections from these neurons interact with the melanocortin receptor neurons and the neurons in the paraventricular nucleus of the hypothalamus. In addition to the hypothalamic control of appetite per se, reward and hedonic processes of "liking" and "wanting" food occur in the ventral striatum of the midbrain in conjunction with the mesolimbic dopamine system. In addition, the corticolimbic system of reward is controlled by areas in the prefrontal cortex, which integrates sensory, emotional, and cognitive information to coordinate behavioral responses (Lenard and Berthoud, 2008). Hence, the homeostatic control of energy balance fits into the larger decision scheme of choice behavior via a complex neural system.

METHODS TO ASSESS ENERGY BALANCE

Assessing Caloric Intake

In animal studies, caloric intake can be quantitatively monitored by measuring the amount of food consumed by animals in metabolic cages. Caloric intake can be derived by multiplying the quantity (grams per day) of diets consumed with the caloric density of the diet. Knowledge of caloric intake is important in many experimental designs where pair-feeding a parallel cohort of animals is necessary. In clinical studies, assessment of caloric intake can be performed in a number of ways, each with its strengths and limitations. A prospective method to collect information about current intake is maintenance of *food records*. These are usually carried out for a specific duration of time (3 to 7 days, generally including both week and weekend days) during which a written record of all food and beverages consumed is maintained. Quantification is performed by estimation of weights or actual weighing of foodstuff, and hence food records provide both qualitative and quantitative data. Advantages include high reliability, as records do not rely on memory but will be more detailed and accurate records of diet and nutrient intake. However, weighed records are both labor and cost intensive and place higher burden on participants. Habitual eating habits can be influenced by the process of recording, and the reliability of the method decreases over long periods of data collection. Collected data are analyzed using a nutritional database such as the Nutrition Data System for Research (University of Minnesota). Several methods of dietary assessment rely on retrospective collection of food intake. The *diet history* and *food recall* are commonly used methods in clinical research, where a trained individual obtains details of participant's habitual dietary intake in-person or over the phone. Details may include portion sizes, cooking methods, and patterns of eating. The techniques allow a large amount of descriptive data to be collected. Most usually, the interviewer incorporates a 24-hour or 3-day window in which detailed recall is obtained. Burden on the participant is low; however, the technique involves considerable training and time on the part of the researcher. Recall interviews can sometimes be time-consuming and several recalls may be necessary to obtain useful information. Again, analysis of the collected data using a nutritional database is necessary to get quantitative measures of nutrient and caloric intakes. *Food frequency questionnaires* (FFQ) are tools that can be self-administered or provided in an interview setting to participants. FFQ collect information about consumption of each food from a

list of foods over a specified period of time (e.g., last 6 months). They are devoid of specific data regarding the portion sizes and cooking method and are not an appropriate method for quantifying intakes. However, FFQ are useful in gathering information on long-term food patterns, in a low-burden and inexpensive method. Both of these methods are merely estimations and can have significant errors. With the rapid increase in mobile devices and smartphones a number of research and commercial "apps" have been developed to assess and track caloric and nutritional intake by adapting the principles of food diaries and the convenience of digitally capturing images of meals.

Assessing Caloric Content of Foods

Accurate assessment of the caloric value of foods is essential for effective nutritional management in clinical and public policy arenas. Classical investigations by Professor Atwater and his colleagues providing the general calorie factors of 4, 9, and 4 for the major sources of energy—carbohydrate, fat, and protein—have been widely used. Both fats and carbohydrates can be completely oxidized to water and carbon dioxide, while protein is incompletely oxidized and partly excreted from the body as urea. The heat released by combustion of a food in a bomb calorimeter is a measure of its gross energy. However, not all the ingested energy will be available for metabolism and digestible energy refers to the fraction following losses of energy as fecal energy and gases from microbial fermentation. The truly metabolizable energy can be derived by accounting for lost energy in urine (mainly from nitrogen) and on the body surface. Analytical methods to determine the macronutrients in food, protein, fat, and carbohydrates in addition to alcohol and other organic acids have been described widely (Tontisirin et al., 2003). Protein content is mainly determined via estimating nitrogen content by either the Kjeldahl method or hydrolysis of proteins into amino acids and then measuring concentrations using gas or high-pressure liquid chromatography. Fat content can be assessed by measuring the sum of methanol–chloroform extractable total fatty acids that can be expressed as triglyceride equivalents. Total fat can also be assessed by gravimetric methods. Carbohydrate content is generally measured by difference as the remaining energy after accounting for protein, fat, alcohol, and ash. This measure of carbohydrate included energy from fiber as well as some components that may strictly not be carbohydrates (organic acids).

Assessing Energy Expenditure

The process of oxidative phosphorylation couples the oxidation of nutrients with the synthesis of high-energy molecules (viz. adenosine triphosphate [ATP]), the main energy currency of the cell. The energy stored with these molecules is utilized to power all the biochemical processes in cells, which encompass metabolism, growth, and cell division. The total energy expenditure (TEE) or metabolic cost for an average adult ranges from 1500 to 3000 kcal/day. A calorie is defined as a unit of energy that is required to raise the temperature of 1 g of water by 1°C. TEE is primarily composed of three components: (1) basal energy expenditure, (2) thermic effect of food (TEF), and (3) energy expenditure associated with physical activity (EEPA). While most of the variance in daily TEE is accounted for by the three aforementioned components, a small fraction of energy expenditure is accounted for by adaptive thermogenesis (energetic cost of cold adaptation). Basal energy expenditure, also called as resting energy expenditure (REE), is the energy expended when the individual is lying down and at complete rest, generally after sleep in the postabsorptive state. REE accounts for almost 60% of TEE (Gropper et al., 2005). A close surrogate of REE is the resting metabolic rate (RMR). TEF, which accounts for 10% to 15% of TEE, is the energy expenditure associated with the digestion, absorption, and storage of food. EEPA consists of (1) expenditure related to planned exercise and (2) nonexercise activity thermogenesis (NEAT). The former refers to purposeful physical activity, which varies in most individuals and is negligible in individuals who do not participate in exercise. However, even in individuals who do undertake regular exercise, NEAT contributes the greater proportion to EEPA. NEAT includes all energy expenditure from occupational and leisure activities (sitting, climbing stairs, walking, fidgeting, etc.).

Components of energy expenditure can be measured using either (1) direct or (2) indirect calorimetry. The basic principle in direct calorimetry is to measure the actual heat produced by the organism in a highly controlled environment as an estimate of energy expenditure. In large organisms (such as human subjects) direct calorimetry is generally impractical due to the large inherent capacity to store heat. Further, due to limitations in the design, complexity, and cost of carrying out direct calorimetry, this methodology is seldom utilized. The most commonly used methods to estimate energy expenditure, therefore, involve indirect calorimetry. Because most aerobic organisms derive energy from oxidation reactions, consumption of oxygen can serve as reliable surrogate for heat production. Using experimentally derived estimates for energy yields per mole of oxygen for the main fuel substrates, heat production can be calculated based on the quantity of oxygen consumed. Indirect calorimetry can be coupled with specific tracer techniques to examine the utilization and metabolism of specific substrates in both whole-body and tissue-specific compartments. The ratio of carbon dioxide expired and oxygen consumed is called the respiratory quotient (RQ). RQ estimates can be useful in understanding both energy expenditure and overall substrate oxidation. An RQ value of 1.0 suggests that carbohydrate is being oxidized, because under these conditions the amount of oxygen required for oxidation of glucose is equal to the amount of carbon dioxide produced. The representative average RQ values for carbohydrate, fat, and protein are 1.0, 0.7, and 0.8, respectively. Indirect calorimetry can be assessed in animals by placing them in closed chambers in which airflow is controlled at specified flow rates. Oxygen and carbon dioxide concentrations are assessed using gas analyzers to calculate RQ values. Specialized chambers that are commercially available integrate measurement of body weights, food and water intake, activity, and oxygen consumption in a single chamber.

In human subjects, the same principle is utilized to assess oxygen consumption in a variety of designs. A simple metabolic cart can be utilized to assess basal metabolic rate (BMR) in individuals over a short 30-minute period while the individual is in the supine position, but not asleep. Estimates of 24-hour RMR can be calculated by extrapolation. Metabolic carts can be adapted to estimate energy expenditure during physical activity such as treadmill running to estimate maximal oxygen consumption (VO_2 max). However, these measurements only estimate the REE component of TEE. Room calorimeters allow estimating the true TEE by measuring oxygen consumption during all aspects of free living, including postmeal thermic expenditure and during physical activity. These studies require the participant to be isolated in a room calorimeter and are expensive to undertake and maintain. Another method to estimate TEE in free-living subjects utilizes measurement of stable isotopes $^2H_2$ (deuterium) and ^{18}O. In this technique, referred to as "doubly labeled water," a stable isotope of water is given to individuals ($H_2{}^{18}O$ and ^2H_2O) and the disappearance of the labeled tracer in blood and urine is assessed over a 3- to 6-week time period.

The labeled water incorporates into the body water pool and estimates either the water turnover alone (^{2}H label) or the turnover of water and production of CO_2 (^{18}O label). The difference between the two rates of loss of the two labels corresponds to the rate of production of CO_2. The amount of oxygen consumed is indirectly calculated via food records (food quotient) over the assessment period. RQ and energy expenditure can then be calculated using the volumes of oxygen and carbon dioxide. RMR estimates can also be calculated nonexperimentally based on derived equations. Equations such as the Harris–Benedict equation and the Mifflin–St. Jeor equation utilize the person's body weight, body surface area, age, gender, and height (Mifflin et al., 1990).

Assessing Body Composition

Body composition assessments are aimed at describing the overall mass of an individual organism in terms of its molecular or nutrient components: water, fat mass, lean mass, protein, and minerals. In a simple two-compartment model of body composition assessment, total body mass is divided into fat mass (essential and nonessential fat) and fat-free mass (including lean mass and water). Lean mass in this scenario includes protein, carbohydrate, and minerals. A number of techniques have been developed to indirectly assess either specific components or all measures of body composition.

Anthropometric Analysis Body mass is an obvious, but poor surrogate to relative fat mass. While individuals with greater body weight (mass) per height tend to have greater fat mass, total body weight may also be determined by increased muscle mass. Taller people on average have greater weight, and weight and/or body composition also change more dynamically with age. Hence, the simplest indirect measure of body fatness is the relative proportion of weight to height, more commonly referred to as body mass index (BMI). BMI is derived by ratio of mass (in kilograms) and square of height (in meters). The advantage of BMI is that it is easy to compute and large worldwide reference data sets exist. BMI, however, is only an estimate and because BMI does not always reflect fat mass, care must be taken when using BMI as a fat index. Other anthropometric estimates of body composition include measurement of skin folds and circumference at various sites (abdomen, waist, hip). The general assumption is that total body fat is proportional to the fat deposited beneath the skin. Measurements can be analyzed by utilizing several regression models that predict percent body fat. Five commonly employed sites include triceps, subscapula, suprailiac, abdomen, and thigh. While the technique is inexpensive to perform, sites chosen for analysis and skill of the anthropometrist influence the accuracy of the results.

Hydrodensitometry The principle used to calculate body density using hydrostatic weighing has been known since antiquity when the Greek mathematician Archimedes showed that the density of an object is the ratio of its weight in air to its loss of weight in water. Using the density of the whole body and correcting for residual air in the lungs and GI tract, the relative body fat can be estimated using derived equations by Siri or Brozek (Nord and Rayne, 1995). This procedure is also known as underwater weighing.

Air Displacement Plethysmography This procedure employs the same principles as underwater weighing described above, except rather than the body displacing water, it displaces air. This allows the body volume to be calculated and then body fat can be calculated. This is probably the most accurate, precise, and cost-effective measure of total body fat, and is employed widely in clinical research in the United States.

Absorptiometry This is one of the most widely used tools in assessing body composition. In this technique imaging is performed throughout the entire body by a photon beam. Most investigations using this technique use either a dual-photon source (gadolinium) or x-ray at two different energy levels (dual-energy x-ray absorptiometry [DXA]). Hence, this allows imaging of both soft tissues and bone. The attenuation of the x-ray signal received on the detector is proportional to the density of the tissue. Percentage of body fat, lean tissue, and bone mineral density can be computed for the whole body or specific sites based on the analysis of images.

Computerized Tomography While utilizing similar principles of differential x-ray attenuation through a body, computerized tomography is used to produce three-dimensional "slices" or cross-sectional images of the subject. This is made possible by positioning the x-ray source and detectors on opposite poles of a circular tube within which the subject is imaged. The ability to generate 3D images allows regional localization of adipose tissues, muscles, and organs (liver). Using the image data, percent body fat and lean mass can be calculated.

Nuclear Magnetic Resonance Nuclear magnetic resonance (NMR) works by interpreting radio-frequency signals of excited nuclei in an external magnetic field. The physical characteristics of the hydrogen atom differ when the hydrogen is located on protein, fat, or water and this can be detected and quantitated to determine body composition. Magnetic resonance imaging (MRI) is an extremely powerful imaging technique with high-resolution capacity and employed widely as a clinical diagnostic tool. Images acquired are three-dimensional allowing detailed analysis of body composition and regional fat and lean mass distribution with depots and ectopic deposition within tissues. While MRI has several advantages in terms of assessing the distribution of body fat, its expense relative to NMR makes it less used, and other considerations such as the requirement for the participant to lay still during the scanning period and the extreme noise make MRI less applicable than NMR for children.

Electrical Impedance Bioelectrical impedance analysis (BIA) and total body electrical conductivity (TOBEC) measure total body composition based on measuring electrical impedance (the inverse of conductance) of an electric current passed through the body. The conductance of a weak painless current through the body (which serves as an electrolytic medium) is utilized to infer lean body mass and fat mass. Lean mass has more water and greater conductivity than fat mass, and predictive equations are employed to derive fat and lean body mass.

Total Body Water Body fat and lean mass can be calculated by estimating total body water using stable isotopes. Dilution of water containing specific concentrations of labeled isotope (either deuterium or ^{18}O) is usually assessed. Concentrations of isotopes are measured in blood or urine over a timecourse following a 2- to 6-hour equilibration period. Because body water occupies 73.2% of lean mass, fat-free mass can be computed based on total body water. Using a three-compartment model fat mass can be calculated. The method is significantly influenced by hydration status and assumptions are confounded by water present in fat tissue. While the cost of chemicals and collection of samples is not high, analysis of stable isotopes can be expensive.

Assessing Physical Activity

Accurate quantification of physical activity in free-living subjects is challenging. Methods utilizing self-reported diaries and questionnaires tend to overestimate physical activity. Devices such as

accelerometers and pedometers can be utilized to empirically estimate activity. Accelerometers are versatile and cost-effective and can measure activity with little subject burden. Existing accelerometers and wearable fitness trackers come in varying degrees of sophistication from simple pedometers that count steps to models that can assess motion in three dimensions. An important challenge in utilizing accelerometers is to convert the count data into energy expenditure, which is done using different regression models. A widely used and lay-friendly translatable "unit" of ambulatory physical activity is the number of steps in a unit of time (steps/day).

BIOLOGY OF OBESITY

Obesity Risk: Genes, Epigenetics, and Fetal Environment

Access to plentiful food has been unpredictable throughout most of human (and animal) developmental history, marked by periods of feast or famine. In evolutionary terms, fitness and survival of an individual were likely to be closely related to the ability to maximally seek, acquire, consume, and store energy (as fat) when food was available, and to select for mechanisms that reduce energy expenditure during times when food is scarce. Thus, selection favored so-called thrifty genes that orchestrate anabolic processes over energy-consuming ones and provide selective advantage to those who possessed them during periods of food deprivation (Neel, 1962). However, the advent of agrarian lifestyle and recent industrialization has meant that much of the developed and emerging world now has a drastically altered environment. Food is generally available for most people and our lifestyles require less physical activity and exertion. Hence, the genetic legacy of once beneficial thrifty genes placed in an environment of caloric abundance acts as a powerful engine for weight gain, obesity, and its associated metabolic dysfunction.

Recently, questions have been raised whether the selection of thrifty genes occurred because of a true advantage contributing to survival. Speakman has proposed that natural variation and random mutation (genetic drift) in genes controlling hypothalamic energy balance set-points occurred in human evolution as human beings developed fire and social behaviors, and were released from risk of predation. This theory, referred to as the "drifty gene" hypothesis, better explains why even in societies where obesity is high, not everyone becomes obese (Speakman, 2008). Obesity is a highly heritable trait and studies comparing monozygotic with dizygotic twins indicate that 40% to 75% of the interindividual difference in trait is accounted for by genetic variability. Several genes whose disruption causes severe monogenic forms of familial obesity have been described. Remarkably, most of these genes impair central control of food intake. However, the genetic basis of nonsyndromic (common) obesity has remained elusive.

Recent genome-wide association studies (GWAS) have been highly effective in identifying common genetic variants that impact adiposity and other aspects of the metabolic syndrome (MetS). To date 50 such obesity-associated loci have been identified with high confidence (O'Rahilly and Farooqi, 2008). Of these the FTO (fat mass and obesity associated) is unequivocally associated with increased risk of obesity. Individuals who are homozygous for the high-risk (AA) allele weigh on average 3 kg more than individuals who do not carry any risk allele. New meta-analysis of GWAS including about 250,000 subjects has revealed 18 novel loci associated with BMI. Overall, the presently identified loci in combination still explain only a small proportion of obesity. Epigenetic regulation of gene expression is another area that might explain the underlying differences in susceptibility to obesity. Epigenetics is loosely defined as heritable changes in modifications to the DNA that do not alter the DNA sequence. DNA methylation, covalent modification of histone tails that affect chromatin structure and accessibility, and regulation via noncoding RNAs are examples of epigenetic regulation. It is clear that epigenetic mechanisms are involved in basic cell functions including proliferation, differentiation, and growth. Because DNA methylation and histone modifications can also be affected by environmental influences (in utero environment, exposure to xenobiotics, stress), it is plausible that interaction of certain risk alleles and epigenetic mechanisms are responsible for susceptibility to obesity.

The incidence of obesity continues to rise and prevalence even among infants is rapidly rising. As for many chronic diseases, it is now widely accepted that increased susceptibility to obesity can be programmed in utero and early postnatal life. This hypothesis referred to as the "developmental origins of health and disease" is derived from the findings by Professor David Barker and colleagues at the University of Southampton, who discovered an inverse relationship between birth weight and risk of mortality due to coronary heart disease (Barker et al., 1989). Over the last two decades, epidemiological studies have extended the initial associations between birth weight and later cardiovascular disease to include associations between early growth patterns and risk for hypertension, insulin resistance, type 2 diabetes, and obesity in later life. Experimentally manipulating birth weights in a variety of animal models (rats, mice, sheep, pigs) also recapitulates the developmental programming phenotype (McMillen and Robenson, 2005). Another important influence on risk of obesity in later life is maternal body composition (fat mass) at conception and gestational weight gain. Studies in women and experimental models clearly indicate that maternal diet and body composition during pregnancy influence aspects of metabolism and appetite regulation in the offspring (Shankar et al., 2008). The mechanisms of such programming presumably involve epigenetic mechanisms.

TOXICITY RELATED TO EXCESS CALORIC INTAKE/OBESITY

Many of the adaptive, physiological responses to a positive energy balance produced as a result of overeating and inadequate physical activity result in toxicity over the long term. Short-term coordinated changes in metabolic pathways in white adipose tissue in response to overfeeding result in excess energy storage in the form of triglycerides and increased size of preexisting adipocytes (hypertrophy), and this also leads to formation of new adipocytes through hyperplasia (Virtue and Vidal-Puig, 2010). However, management of excess ingested energy over the long term can be complex. Under such conditions, the efficiency of energy storage in adipose tissue is decreased and the body has to resort to several different options to store energy in addition to fat, such as in ectopic sites, which may in fact be detrimental. As plasma concentrations of nonesterified fatty acids (NEFA) increase as a result of ingestion of high-fat diets and as a result of hydrolysis of triglycerides in the fat, triglycerides begin to accumulate in nonadipose tissues such as the liver, skeletal muscle, and the pancreas as lipid droplets. The presence of excess NEFA and lipid metabolites in these tissues results in direct and indirect toxic actions leading to insulin resistance, inflammation, and tissue damage.

In addition, adipose tissue from obese individuals releases chemokines and cytokines, the so-called adipokines, which contribute to a state of "metabolic inflammation" (Dulloo et al., 2010;

Gustafson, 2010). Fat is also an endocrine organ and the pattern of adipokines produced by adipose tissue in obesity differs substantially from that seen in lean individuals (Cornier et al., 2008).

NEFA and the other factors released from adipose tissue contribute to the development of the metabolic syndrome (MetS) in some overweight and obese individuals. This is a cluster of components including insulin resistance, disruptions in lipid homeostasis (dyslipidemia), and elevated blood pressure that substantially increase the risk for development of cardiovascular disease and type 2 diabetes. MetS is also associated with other comorbidities including nonalcoholic fatty liver disease (NAFLD) and reproductive dysfunction and elevated serum insulin in response to insulin resistance contributes to increased cancer risk associated with obesity. As a consequence, overall mortality is increased and life span is shortened with increasing caloric intake, body weight, and adiposity, whereas caloric restriction (CR), at least in animal models, has been shown to substantially increase life span.

Adaptation of Liver and Adipose Tissue to Excess Calories

Triglycerides and glycogen are used by the body to store excess caloric energy. This is a homeostatic mechanism that maintains energy sources such as blood glucose levels between meals. Dietary fats are transported in blood from the gut to the liver and adipose tissue by lipoprotein particles called chylomicrons. In both tissues, local hydrolysis of triglycerides in the capillary bed by the enzyme lipoprotein lipase results in the release of free fatty acids that are subsequently taken up into hepatocytes and adipocytes via fatty acid transport proteins (FATPs) and the scavenger receptor CD36. As they enter the cell, free fatty acids that are toxic are immediately conjugated with acetyl CoA and are bound to intracellular fatty acid–binding proteins before reesterification with glycerol to form triglyceride lipid droplets in the cytosol. Such droplets are highly dynamic and are coated with PAT proteins (named after *p*erilipin, *a*dipophilin, and the *t*ail-interacting protein). Adipophilin and perilipin have important roles in droplet stabilization and regulation of triglyceride turnover. The hepatocyte cytosol contains many small droplets that vary in size depending on the length of time after a meal, dietary fat to carbohydrate ratio, type of dietary fat, and overall caloric intake relative to metabolic requirements. The small hepatic lipid droplets function as a temporary energy storage site, whereas in adipocytes the small lipid droplets fuse to form a single large storage droplet and can serve as a longer-term storage site. In the hours after a meal, triglycerides from the hepatic droplets are incorporated into the lipoprotein VLDL, which is secreted into the plasma and which transports hepatic triglycerides to the adipose tissue for storage. Removal of triglycerides from VLDL by lipoprotein lipase in adipose and other peripheral tissues results in generation of the more dense lipoprotein LDL, which is subsequently recycled by the liver as a result of endocytosis on binding to the LDL receptor (Olson, 1998).

Obesity is often associated with consumption of high-fat diets. In addition to being more energy dense, recent studies have suggested that, at least in part, the obesogenic effects of these diets stem from changes in composition of the gut microbiota (Shen et al., 2014). Transplantation of gut microbiota from donor mice made obese by high fat feeding into germ-free mice has been shown to increase adiposity in these mice relative to mice receiving gut microbes from lean mice. Decreases in populations of Bacteroidetes and increases in populations of Firmicutes in the gut of obese animals change the spectrum of microbial fermentation products, which may in turn change energy harvest and expenditure, alter satiety signals such as the gut peptides YY or ghrelin, and impact insulin action through changes in synthesis of the gut peptide, glucagon-like peptide (GLP-1). In addition, increased bacterial synthesis of short-chain fatty acids (SCFA) may increase obesity as they are substrates for lipid synthesis.

However, obesity can also develop from excessive caloric intake of any food energy source, including carbohydrates and proteins. Although overall consumption of dietary fat has declined in the United States over the past two decades, the proportion of obesity has increased to epidemic levels. In part, this is due to excessive intake of simple carbohydrates that have increased as dietary fat consumption has decreased. Dietary carbohydrates are converted to monosaccharides, mainly glucose and fructose, which are further metabolized in the liver and peripheral tissues. Excess glucose can be stored in the liver in the form of the glucose polymer glycogen that accumulates as cytosolic granules and can make up as much as 7% of liver weight. However, the majority of excess hepatic glucose is metabolized via glycolysis and the citric acid cycle to acetyl CoA and is shunted into de novo fatty acid and triglyceride synthesis.

Recent DNA microarray analysis of gene expression in human adipose tissue biopsies suggests that coordinated upregulation of lipogenesis occurs in fat rapidly and directly as a result of increased caloric intake independent of changes in body weight (Franck et al., 2011). Evidence for increases in adipose tissue glucose transport, and fatty acid and triglyceride biosynthesis has also been obtained from microarray analysis of fat from rats overfed a mixture of simple carbohydrates and fat (Shankar et al., 2010). The increase in triglyceride synthesis in both the liver and fat after consumption of excess calories appears to be driven by activation of two important diet-sensitive transcription factors: sterol regulatory element–binding protein 1c (SREBP-1c) and carbohydrate response element–binding protein (ChREBP) (Postic and Girard, 2008), and this process in fat ultimately drives adipose tissue hypertrophy. In addition to fat cells getting larger, excess calories also trigger proliferation and differentiation of preadipocytes in adipose tissue depots into new adipocytes, a process known as hyperplasia. However, the degree to which hyperplasia contributes to the ability of fat stores to expand in response to the need to store excess energy relative to hypertrophy remains unclear.

What is clear is that in some individuals, there is a limit to which adipocytes can expand safely and that when this limit is reached, toxicity results. This limit appears to depend on which fat depot the adipocytes are in. Subcutaneous adipocytes can attain a greater size than adipocytes in visceral fat and this may explain why metabolic dysfunction and diseases such as type 2 diabetes are linked to visceral adiposity. Hypertrophic adipocytes develop ultrastructural abnormalities including calcium accumulation and cholesterol crystals and show evidence of oxidative and endoplasmic reticulum (ER) stress ultimately leading to cell death and release of intracellular components that can serve as metabolic damage–associated molecular patterns (DAMPs) (Giordano et al., 2013; Khan and Wang, 2014). Recent data from high fat-induced obese mice suggest that DAMP release from dying adipocytes results in activation of the Nod-like receptor NLRP3 inflammasome in remaining hypertrophic adipocytes. This amplifies obese adipocyte cell death by pyroptosis, a form of proinflammatory programmed cell death mediated via NLRP3-dependent caspase 1, and also results in a sterile inflammatory response characterized by activation of interleukin 1β (Giordano et al., 2013). Macrophage infiltration of metabolically stressed adipose tissue to remove cell debris associated with adipocyte death results in further inflammation and the formation of characteristic crown-like structures.

When fat mass increases excessively, adipose tissue also undergoes extensive structural remodeling. An extracellular matrix (ECM) with high concentrations of collagen fibrils and fibronectin appears to be essential for maintenance of the structural integrity of adipocytes and for preadipocyte differentiation (Divoux and Clement, 2011). However, at the point when adipocytes reach a certain size limit within a particular fat pad, hypoxia appears to develop possibly as a result of restricted blood flow. This triggers expression of the transcription factor hypoxia-inducible factor 1α (HIF-1α). Evidence from HIF-1α transgenic and knockout mice suggests that HIF-1α regulates inappropriate ECM remodeling and development of fibrosis in adipose tissue in response to hypoxia and obesity (Halberg et al., 2009). Fibrosis has been reported to be increased in subcutaneous adipose tissue from obese subjects compared with lean subjects both by staining of collagen fibrils and by analysis of col6a3 gene expression. The percentage of fibrosis in white adipose tissue has further been shown to correlate with inflammation in morbidly obese subjects (Divoux and Clement, 2011). Further evidence linking adipose tissue ECM with limitations in the ability of fat pads to expand to store excess caloric energy and for limited adipocyte hypertrophy to precede the development of obesity-linked pathologies such as inflammation and MetS comes from studies with mice in which genes involved in ECM formation have been knocked out. The protein SPARC is required for appropriate collagen synthesis during ECM remodeling. Both SPARC$^{-/-}$ mice and obesity-prone ob/ob mice where the collagen VI gene has been deleted display increased adipocyte and fat pad size, loose ECM structure, and reduced inflammation and metabolic disturbances after high-fat feeding. It is thought that complex interactions between enlarging adipocytes and a fibrotic ECM trigger activation of MAP kinase pathways such as c-Jun N-terminal kinase (JNK) resulting in development of adipocyte insulin resistance (Divoux and Clement, 2011) (see Fig. 28-1).

Ectopic Fat Deposition

In general, there is a positive correlation between increased BMI and inappropriate accumulation of lipids in tissues other than fat. The major sites for this ectopic fat deposition are the liver and skeletal muscle. However, lipid accumulation in other tissues such as small intestine, pancreas, and uterus has also been reported to be associated with chronic consumption of high-fat diets and development of obesity. Correlation between central (visceral) adiposity, waist circumference, and ectopic fat deposition is better than for BMI and is also highly correlated with progressive insulin resistance. However, the relationship between adiposity, ectopic fat accumulation in the liver and muscle, and insulin resistance is highly complex and is strongly affected by diet composition, exercise, and race (Lara-Castro and Garvey, 2008).

In the liver, intrahepatocellular lipid accumulation, also known as fatty liver, or steatosis, is defined as an increase in hepatic lipid content above 5% by weight and is characterized in paraffin-stained sections by the appearance of multiple round empty vacuoles in hepatocytes displacing the nucleus to the periphery of the cell. To confirm that steatosis is actually present, additional staining of frozen sections for triglycerides using stains such as Oil Red O is required. Abnormal

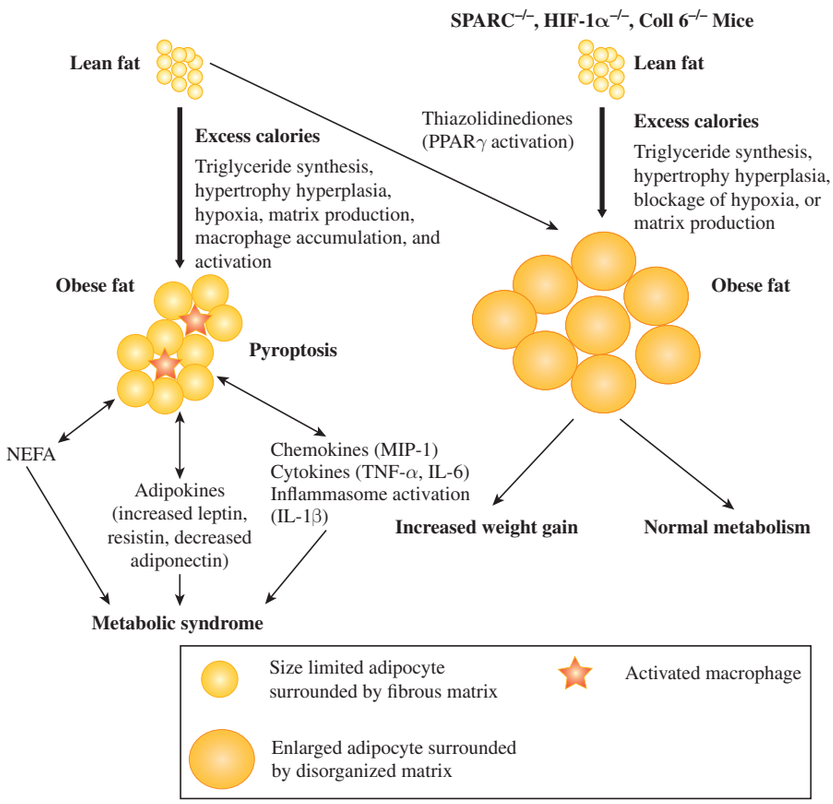

Figure 28-1. *Effects of excess calories (energy) on fat morphology under conditions leading to metabolic syndrome (left) or following stimulation of adipocyte differentiation and hyperplasia by thiazolidinedione treatment/in knockout mice incapable of normal responses to hypoxia (HIF-1α$^{-/-}$)/in knockout mice incapable of normal extracellular matrix production (SPARC$^{-/-}$, Coll 6$^{-/-}$) (right).*

lipid accumulation in the liver in the absence of heavy alcohol usage is referred to as nonalcoholic fatty liver disease (NAFLD) and is associated with a wide spectrum of hepatic dysfunction. The incidence of NAFLD in the general population including children has increased in line with increasing incidence of obesity and is observed in more than 50% of adult obese patients (Browning et al., 2004). Simple steatosis is generally reversible with weight loss and/or lifestyle modification (diet and exercise). However, a small proportion of patients progress to more severe liver pathologies (see the section "Nonalcoholic Steatohepatitis" later in this chapter). Hepatic lipid accumulation can occur as a result of one or more of the following: (1) increased fatty acid supply to the liver and increased fatty acid transporter expression; (2) increased de novo fatty acid and triglyceride synthesis; (3) decreased fatty acid oxidation; and (4) decreased synthesis and/or secretion of VLDL. Which of these processes predominates depends on the degree of obesity, total caloric intake, and diet composition. As the capacity of adipose tissue to expand is compromised with increasing BMI and insulin resistance develops in adipocytes, there is an increase in plasma nonesterified free fatty acids (NEFA) as a result of increased hydrolysis of triglycerides in fat by two enzymes—hormone-sensitive lipase and adipose triglyceride lipase. Increased hepatic exposure to NEFA derived from adipose tissue or from dietary fats has been reported to increase fatty acid transporter expression in hepatocytes (Baumgardner et al., 2008a; Marecki et al., 2011). In contrast, excess calories in the form of simple carbohydrates results in increased de novo hepatic fatty acid synthesis (Shankar et al., 2010). The type of dietary fat can also influence the development of steatosis. For example, it has been shown that saturated and polyunsaturated fatty acids can interfere with VLDL secretion relative to monounsaturated fatty acids via different mechanisms; while polyunsaturated fatty acids provoke oxidative stress and degradation of ApoB100 in hepatocytes, saturated fatty acids appear to block VLDL secretion via stimulation of an unfolded protein response and ER stress (Pan et al., 2004; Caviglia et al., 2011). In addition to increased NEFA, adipose tissue inflammation also appears to significantly contribute to development of NAFLD. Positive correlations have been reported between expression of macrophage markers in adipose tissue and liver fat content independent of total fat mass (Lara-Castro and Garvey, 2008).

Moreover, disrupted adipokine secretion also plays a role. The adipokine adiponectin acts on the liver to inhibit fatty acid synthesis and increase fatty acid degradation through activation of the AMP kinase cascade, downstream inhibition of SREBP-1c, and activation of the transcription factor peroxisome proliferator–activated receptor α (PPARα). Reduced serum concentrations of adipokine adiponectin that accompany development of obesity will result in increased hepatic fatty acid synthesis and reduced fatty acid degradation and thus contribute to development of steatosis (Shankar et al., 2010).

The other major site of ectopic fat deposition in obesity is skeletal muscle in the form of intramyocellular lipid (IMCL). Skeletal muscle contains an intracellular pool of stored triglyceride that exchanges with circulating free fatty acids. Although older methods such as biochemical extraction and computer tomography scans could quantitate muscle tissue triglycerides, more recent approaches such as Oil Red O staining of frozen sections and proton NMR spectroscopy are capable of quantifying IMCL distinct from extramyocellular fat in muscle tissue. Using these methods, IMCL has been shown to positively correlate with visceral adiposity. Various mechanisms have been proposed to underlie accumulation of IMCL in obesity. In adults it has been suggested that changes in intracellular distribution of the fatty acid transporter CD36 from soluble to membrane-associated pools are responsible for increased import of NEFA and triglyceride accumulation (Nickerson et al., 2007). In contrast, data from a pediatric model of obesity demonstrated increased CD36 mRNA and protein expression in skeletal muscle associated with appearance of IMCL (Marecki et al., 2011).

Metabolic Syndrome

The development of central obesity as a result of overnutrition and a sedentary lifestyle leads to a clustering of metabolic and physiological components in some individuals that is associated with a doubling of cardiovascular disease risk and a fivefold increase in incidence of type 2 diabetes originally described as "syndrome X" by Reaven (1988) or "insulin resistance syndrome" and more recently as metabolic syndrome (MetS) (Cornier et al., 2008). Although the definition of MetS differs by health agency, all tend to agree that the core components include central obesity (waist circumference), insulin resistance (increased fasting glucose above 100 mg/dL and increased fasting insulin, as a result of impaired glucose uptake into skeletal muscle/fat and increased glucose output by the liver, resulting from end-organ insensitivity to insulin), dyslipidemia (decreased serum HDL below 40 mg/dL in men and 50 mg/dL in women, and increased serum triglycerides above 150 mg/dL), and hypertension (blood pressure higher than 130/85). The worldwide incidence of MetS is increasing rapidly with the obesity epidemic and is influenced by sex, age, and ethnicity. In the United States, prevalence of MetS is around 30% with higher rates in Mexican Americans than in white non-Hispanics and African Americans and increases with age into the sixth decade. Although there are no established criteria for MetS in children and adolescents and prevalence values depend on age, population studied, and definition, among adolescents, overall incidence has been estimated to be 4.2% rising to 28.7% in those classified as obese (Cook et al., 2008).

Although there does not appear to be a common unifying pathophysiological cause for all components of MetS, central obesity and insulin resistance appear to be the major drivers of this condition. The majority of obese individuals are insulin resistant but the correlation between obesity and insulin resistance is better for abdominal obesity/waist circumference than it is for overall BMI and better for whites than for African Americans. Moreover, weight loss following the feeding of low-calorie diets or following bariatric surgery rapidly leads to marked improvements in insulin sensitivity. However, the relationship between obesity and whole-body insulin resistance is not direct but appears to be mediated through increased circulating fatty acids and ectopic fat deposition particularly in intramyocellular lipid (IMCL) in skeletal muscle (Fig. 28-2). Consumption of a very low calorie diet in obese subjects for as little as 5 days has been shown to produce marked decreases in IMCL and enhanced insulin sensitivity without significant changes in body fat mass (Lara-Castro et al., 2008). It has been suggested that reductions in glucose import into skeletal muscle with IMCL result from inhibition of translocation of the glucose transporter GLUT-4 from cytosolic- to membrane-associated compartments through the action of IMCL metabolites such as diacylglycerol, long-chain fatty acid CoAs, ceramides, and oxidized lipids (Pan et al., 1997). Insulin resistance in muscle is accompanied by evidence of impaired mitochondrial function. However, it is unclear if this is a consequence of or contributor to IMCL (Lara-Castro and Garvey, 2008). Reduced glucose transport also occurs in insulin-resistant adipose tissue itself, and the negative effects of obesity are exacerbated because reduced insulin signaling in adipocytes also enhances expression of hormone-sensitive and adipose triglyceride lipases to further increase the release of NEFA (Cornier et al., 2008).

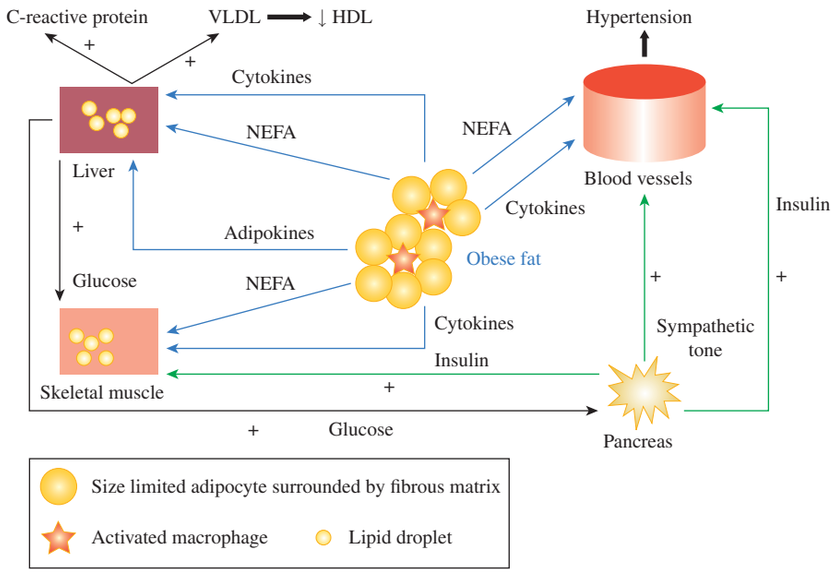

Figure 28-2. *Pathogenesis of metabolic syndrome.*

The relationship between liver steatosis and hepatic insulin resistance is less clear and the question of whether NAFLD is a cause or a consequence of hepatic insulin resistance remains unresolved (Cohen et al., 2011). Insulin resistance in the liver leads to excess glucose production as a result of a reduced ability of insulin to suppress the gluconeogenic enzyme phosphoenolpyruvate carboxykinase (PEPCK). This contributes to systemic hyperglycemia and increased pancreatic insulin production. Insulin resistance and steatosis are strongly correlated and interventions that lead to lower plasma insulin levels also decrease liver triglyceride content. Moreover, patients producing hepatic insulin as a result of metastatic insulin-secreting tumors develop steatosis in the surrounding hepatocytes. However, the suggestion that steatosis causes hepatic insulin resistance is contradicted by data from genetically manipulated mouse models where reduced fatty acid mobilization, reduced fatty acid oxidation, and defective choline synthesis are all associated with development of steatosis, but where hepatic insulin sensitivity is maintained (Cohen et al., 2011).

The dyslipidemia associated with MetS is thought to be a direct consequence of increased VLDL secretion by the liver. Increased serum triglycerides are generally associated with a change in HDL size and lipid composition, and reduction of serum HDL concentration as a result of increased clearance via the kidney. Several different mechanisms have been proposed to explain the rise in blood pressure associated with MetS. Insulin acts both directly as a vasodilator and secondarily to increase sodium resorption from the kidney. Evidence suggests that under conditions of insulin resistance, the vasodilatory effects of insulin are lost while the renal effect on sodium resorption is maintained. In addition, fatty acids can act directly to mediate vasoconstriction and both fatty acids and insulin can increase the activity of the sympathetic nervous system. Adipokines, such as leptin and resistin, have also been implicated in the pathogenesis of obesity-associated hypertension (Cornier et al., 2008).

Therapeutic Options for Managing Metabolic Syndrome

Because it is unclear that there is a unifying mechanism underlying the constellation of metabolic and physiological abnormalities that make up MetS, management can be problematic. Lifestyle modifications in the obese, including diets producing stable weight loss and long-term increased physical activity or bariatric surgery (discussed in the section "Surgical Interventions" later in this chapter), are of benefit in treating all the components of MetS, but suffer from limited compliance and significant risk of complications in the case of surgery. Therefore, routine clinical management of MetS has focused on pharmaceutical therapies for insulin resistance/hyperglycemia, dyslipidemia, and hypertension to reduce the risks of cardiovascular disease and type 2 diabetes.

Several classes of drugs are used to target insulin resistance. Metformin acts on the liver to reduce hepatic glucose production as a result of activation of the AMP kinase pathway (Boyle et al., 2010). Moreover, metformin is relatively nontoxic and has been shown to reduce progression from hyperglycemia to type 2 diabetes and the incidence of cardiovascular disease (Knowler et al., 2002; Ratner et al., 2005). Thiazolidinediones such as pioglitazone and rosiglitazone also improve insulin sensitivity and slow progression of diabetes in about 50% of patients as a result of activation of the transcription factor PPARγ in extrahepatic tissues and increasing circulating levels of adiponectin (Gerstein et al., 2006; Cho and Momose, 2008). However, increased insulin sensitivity is associated with an expansion of adipose tissue and significantly increased body weight because PPARγ regulates adipocyte differentiation. Moreover, a recently discovered adverse effect of thiazolidinediones is increased bone loss and an increased risk of osteoporosis; PPARγ activation in bone inhibits osteoblastogenesis and stimulates accumulation of fat cells in bone marrow (Lecka-Czernik, 2010). Additional concerns have been raised regarding potential for increased cardiovascular problems in patients taking rosiglitazone (Palee et al., 2011).

Dyslipidemia associated with MetS is a major modifiable risk factor for cardiovascular disease. Increased triglycerides and low HDL levels are often accompanied by increased total and LDL cholesterol and LDL is a primary target for cholesterol-lowering therapy. Standard first-line therapy is statin inhibitors of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA), the rate-limiting step in cholesterol biosynthesis, such as atorvastatin (Lipitor®). These compounds improve overall lipid profiles by decreasing LDL concentrations 20% to 40%, increasing HDL 5% to 10%, and decreasing triglycerides 7% to 30% (McFarlane et al., 2002). Although

generally well tolerated, atorvastatin results in muscle or joint pain in 5% of patients. Muscle pain can be an indication of rhabdomyolysis (muscle breakdown). In addition, liver injury as indicated by elevated serum values of liver enzymes such as alanine aminotransferase (ALT) has been reported in some users (Bakker-Arkema et al., 1996). Statins are often used in combination with ezetimibe or niacin to further reduce LDL and triglycerides and raise HDL levels. In addition to statins, high doses of 2 to 4 g of fish oil omega-3 fatty acids such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) have been shown to reduce serum triglycerides by 20% to 40% (Cornier et al., 2008).

Control of hypertension is also the key to prevention of cardiovascular events. Many antihypertensive drugs are available and are taken chronically. The most commonly prescribed are adrenergic β-blockers, which inhibit sympathetic inputs to reduce cardiovascular output and slow heart rate. Despite substantial decreases in systolic and diastolic blood pressure, long-term prospective studies suggest that treated hypertensive men continue to have a much greater risk of stroke and coronary heart disease than normotensive men of the same age in the second decade of treatment (Deshmukh et al., 2008). This may be due to metabolic side effects, particularly increased serum triglycerides and lowering of HDL. In addition, diuretics are often given in combination with β-blockers. This can result in reductions of serum potassium and increased occurrence of gout in patients with marginal uric acid concentrations. Other frontline antihypertensive drugs are the angiotensin-converting enzyme (ACE) inhibitors. ACE inhibitors work on the renin–angiotensin system by preventing the conversion of angiotensin I to angiotensin II and reducing production of the hormone aldosterone. Aldosterone acts to reduce sodium and water excretion and is a direct vasoconstrictor. ACE inhibitors reduce arteriolar resistance, increase venous capacity, and increase cardiac output while increasing sodium excretion. ACE inhibitors in general have favorable effects on lipid profile.

Data linking obesity development and MetS with dysbiosis of the gut microbiota have resulted in increasing interest in the use of probiotics as a potential therapeutic option. Recent studies of probiotic supplementation with a highly proliferative strain of *Bifidobacterium animalis* spp. *lactis* in mice fed high-fat diets resulted in reduced visceral fat accumulation and improved glucose tolerance associated with increased levels of the most abundant bacterial short-chain fatty acids (SCFA), acetate, and an increase in levels of glucagon-like peptide 1 (GLP-1) in both the gut and the plasma. Acetate has been implicated in the protective effects of probiotics. It has been shown to bind to a G protein–coupled receptor GPR43 to inhibit fat accumulation in adipocytes, to potentiate pancreatic β-cell function, and to reduce appetite via a central hypothalamic mechanism (Aoki et al., 2017).

Nonalcoholic Steatohepatitis

As described above, ectopic fat deposition in the liver is strongly correlated with obesity and insulin resistance. Although NAFLD is not considered a core symptom of MetS, it is often a comorbidity. Fatty liver is very common being found in 30% of autopsies and in more than 80% of the obese. However, for reasons that remain unclear, in the majority of cases, steatosis is reversible and relatively asymptomatic. The disease progression of NAFLD begins with simple steatosis which progresses to nonalcoholic steatohepatitis (NASH), which is characterized by cell death, inflammation, and fibrosis, then to cirrhosis in which liver function is significantly impaired, and ultimately to hepatocellular carcinoma (Cohen et al., 2011) (Fig. 28-3). Only about 30% of individuals with NAFLD show evidence of progression of pathology to NASH, and of these only 20% to 30% progress further to cirrhosis within 10 years. Of those with NASH-induced cirrhosis, 4% to 27% ultimately develop liver cancer. NASH was first described by Ludwig et al. (1980) in a group of obese adults without a history of alcohol abuse and has increased in prevalence with the obesity epidemic to about 2% to 3% of the U.S. population. It is also increasingly observed in the pediatric population including cases in children as young as 2 years of age (Loomba et al., 2009). Although steatosis can be diagnosed noninvasively using ultrasound or imaging, improved methods for early detection of NASH are urgently required. Although elevated serum ALT values increase the likelihood of NASH, up to 59% of

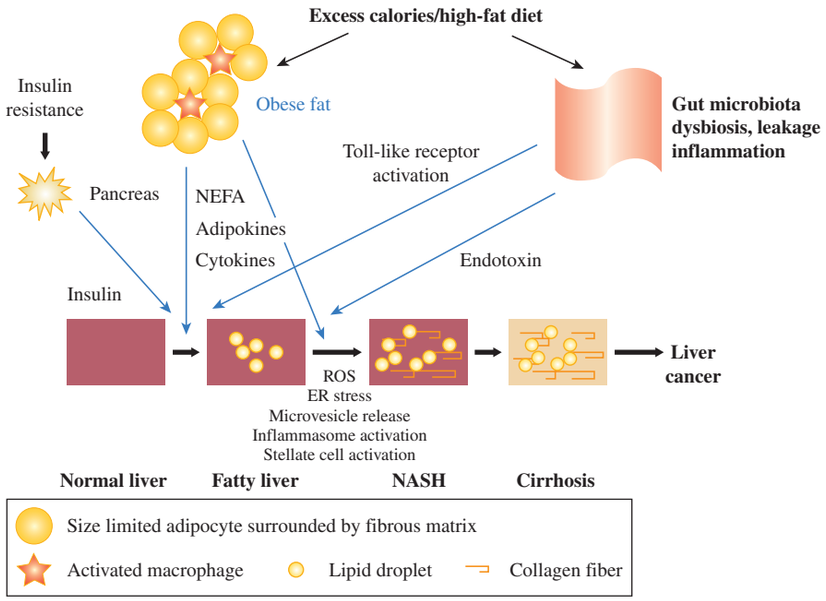

Figure 28-3. *Progression of nonalcoholic fatty liver disease (NAFLD).* ER stress, endoplasmic reticulum stress; ROS, reactive oxygen species.

NASH patients had normal ALT values and at present, only liver biopsy can provide accurate diagnosis.

Our understanding of the molecular mechanisms whereby NAFLD pathology progresses is hampered by lack of an animal model that recapitulates all aspects of the human disease (Hebbard and George, 2011). Until recently, a widely held "two-hit" hypothesis held that progression of NAFLD to NASH requires initial development of steatosis followed by several possible second hits. These include oxidative stress resulting from lipid peroxidation and mitochondrial dysfunction and ER stress triggered by protein misfolding resulting from direct lipotoxicity of saturated fatty acids. In addition, bacterial overgrowth and increased gut permeability resulting from chronic consumption of high-fat diets can increase plasma endotoxin levels resulting in Kupffer cell activation and inflammation. An initiating role for steatosis in NASH progression is supported by human studies of NAFLD heritability. NAFLD, NASH, and cirrhosis cluster in families and one genetic variant consistently associated with appearance of NAFLD is a missense mutation in the *PNPLA3* (adiponutrin) gene. *PNPLA3* has triglyceride hydrolase activity that is lost on mutation, consistent with the accumulation of liver fat. More recent GWA association analysis of SNPs from subjects with biopsy-proven NAFLD has yielded additional genetic variants associated with dysregulated lipid homeostasis. These include lysophospholipase-like 1 (*LYPLAL1*), which like *PNPLA3* is linked to triglyceride breakdown, and glucokinase regulator (*GCKR*), which regulates glucose storage and provides substrates for de novo lipogenesis (Speliotes et al., 2011). Treatment with insulin sensitizers, bariatric surgery, and lifestyle modification (diet and exercise) resulting in weight loss and reduction of hepatic fat content improve NASH liver pathology (Cohen et al., 2011).

More recently the two-hit hypothesis has been modified into a multiple interrelated hit theory as evidence has accumulated that factors derived from obese adipose tissue such as adipokines and the proinflammatory cytokine tumor necrosis factor (TNF-α), activation of the endogenous immune system through Toll-like receptors, ER stress, and signals from the gut microbiota can all increase hepatic fat accumulation (Tilg and Moschen, 2010; Hebbard and George, 2011). The progression of steatosis to necroinflammatory injury and fibrosis in NASH livers appears to depend on oxidative stress mediated by reactive oxygen species generated by cytochrome P450 CYP2E1 and NADPH-oxidase enzymes (Liang et al., 2016; Abdelmegeed et al., 2017). Treatment with dietary antioxidants such as the glutathione precursor *N*-acetylcysteine and vitamin E has recently been shown to prevent increases in serum ALT, suppress hepatic production of TNF, and improve NASH pathology (Baumgardner et al., 2008a, 2008b; Sanyal et al., 2010). Lipid peroxidation resulting from ROS action on accumulated fats has also been linked to NASH progression. Highly reactive short-chain aldehydes such as malondialdehyde and 4-hydroxynonenal (4HNE), which are the end products of lipid peroxidation, accumulate in steatotic livers and can react with cellular proteins to form adducts, especially in the mitochondria. These adducted proteins may have impaired function and may also be recognized as foreign haptens by the immune system triggering an autoimmune response involving the formation of autoantibodies. Consistent with this hypothesis, studies of high fat feeding using genetically manipulated mice made steatotic by loss of the peroxisome proliferator–activated receptor α (PPARα) and unable to degrade 4HNE as a result of deletion of glutathione-*S*-transferase A4-4 have shown greater progression of liver pathology relative to wild-type mice or mice lacking each gene separately (Ronis et al., 2017). In addition, prior immunization with 4HNE-adducted albumin has been shown to exacerbate liver injury in a mouse model of NASH utilizing a methionine- and choline-deficient diet (Sutti et al., 2016). Damage to hepatocytes in steatotic livers has also recently been linked to release of extracellular microvesicles/exosomes containing micro RNAs, and to release of damage-associated molecular patterns (DAMPs), which appear to play a role in development of inflammation including inflammasome activation in other parenchymal cells and resident macrophages (Wan et al., 2016; Cannito et al., 2017).

Development of fibrosis subsequent to NASH appears to involve activation of hepatic stellate cells by the cytokine transforming growth factor β (TGF-β) and factors associated with disruption of lipid homeostasis including the sphingosine metabolite, sphingosine 1-phosphate (Basaranoglu et al., 2013; Mercer et al., 2017). Stellate cell activation is associated with inappropriate secretion of matrix components, particularly collagen, as a result of regenerative wound-healing responses to chronic liver injury. Proliferative regenerative responses also ultimately promote development of hepatocellular carcinomas in NASH patients (Dooley et al., 2009; Matsuzaki, 2009; Nejak-Gowen and Monga, 2011).

Alteration in Drug Pharmacokinetics and Metabolism in Obesity and NAFLD

Obesity and fatty liver disease can have significant effects on drug pharmacokinetics, metabolism, and therapeutic efficacy with the potential to result in adverse drug reactions (Hanley et al., 2010; Merrell and Cherrington, 2011).

The most significant change in drug pharmacokinetics associated with obesity is likely to be in volume of distribution (V_d), and this determines loading dose selection. V_d estimates the extent to which a drug distributes into extravascular tissues and this in turn will depend on the drug's physiochemical properties, binding to plasma proteins, and tissue blood flow (see Chap. 7, "Toxicokinetics"). The V_d of lipid-soluble drugs that partition readily into adipose tissue is likely to be significantly increased in obesity because obese individuals have a larger fat compartment into which the drug can distribute. In contrast, V_d for hydrophilic drugs that do not readily partition into fat may be relatively unaffected (Hanley et al., 2010). For example, while the V_d for the highly lipophilic chemotherapeutic drug docetaxel is increased by more than 400 L in the obese, the V_d for the water-soluble antibiotic daptomycin is increased by only 2 to 4 L. There are little data to suggest that obesity significantly alters drug binding to albumin or other plasma proteins. However, reductions in tissue blood flow and altered cardiovascular function have been observed in obesity and may further alter V_d. Increases in V_d in obesity may significantly alter drug efficacy. For example, the disposition of lipid-soluble oral contraceptives such as ethinyl estradiol has been shown to be altered in obesity and increased weight may be associated with increased risk of failure of contraception. In such circumstances drug loading dose should be adjusted by total body weight or BMI.

The major influence determining the steady-state plasma concentration of a drug in a maintenance dose regimen is clearance (CL). This in turn depends on rate of metabolism and expression of drug transporters. Obesity and NAFLD appear to have variable effects on hepatic phase I and II drug metabolism and on transporters. However, significant species differences in regulation of these enzymes and transporters and lack of appropriate animal models for NAFLD/NASH make extrapolation of much of the experimental data to the clinic problematic (Merrell and Cherrington, 2011). Obesity and NAFLD have been shown to increase expression of the cytochrome P450 enzyme CYP2E1 in both animal models and human clinical studies. CYP2E1 is involved in the metabolism of ethanol, solvents, and volatile anesthetics such as halothane

and enflurane. In contrast, hepatic expression of CYP1A2 that metabolizes approximately 15% of therapeutic drugs including anticoagulants, antidepressants, antihypertensive drugs, and cyclooxygenase-2 inhibitors appears to be consistently suppressed. The effects of NAFLD/NASH on expression of other cytochrome P450 enzymes are inconsistent. However, increases have been observed in expression of other phase I enzymes including NAD(P)H quinone oxidoreductase, the mitochondrial form of epoxide hydrolase, and several aldehyde dehydrogenases in animal models of NAFLD. Less is known about the effects of NAFLD/NASH on drug conjugation and transport. Decreased expression of sulfotransferases has been reported in NASH patients, but effects on drug glucuronidation are inconsistent and glutathione conjugation appears mixed despite observations of GSH depletion in human NAFLD patients. Recent studies in experimental rat models of NAFLD suggest decreased expression of hepatic uptake transporters such as the sodium/taurocholate co-transporting polypeptide (NTCP) and the organic anion transporting polypeptides (OATPs) and increased expression of efflux transporters, such as the multidrug resistance–associated proteins Mrp2, Mrp3, and Mrp4 (Lickteig et al., 2007; Fischer et al., 2009). This was accompanied by a proportional shift in elimination of acetaminophen metabolites from bile to urine (Lickteig et al., 2007).

Drug elimination as measured by half-life is affected by both V_d and CL and thus may also be altered in obesity. Half-life is calculated using the following formula: $t_{1/2} = (\ln 2 \times V_d)/\text{CL}$, and thus changes in both V_d and CL can influence drug half-life. For example, the $t_{1/2}$ of the antianxiety drug diazepam is markedly increased in obese subjects as a result of increased V_d even though CL is unchanged.

Endocrine Dysfunction in Obesity, Metabolic Syndrome, and NAFLD

A wide spectrum of endocrine disruption is associated with obesity and MetS. Obesity in pregnancy can result in many complications including gestational diabetes, pregnancy-associated hypertension, preeclampsia, and fetal abnormalities including neural tube defects, spina bifida, heart defects, and cleft palate (Kulie et al., 2011). In addition, delays in milk production and decreased duration of breast-feeding have been associated with obesity in women as a result of hormonal and metabolic effects on mammary gland development during pregnancy.

As discussed above, hyperglycemia resulting from systemic insulin resistance provokes a compensatory increase in insulin secretion from the pancreas in obese individuals. Hyperinsulinemia then appears to have secondary effects on other endocrine systems. For example, growth hormone (GH) secretion is dramatically suppressed by obesity in both adults and children, but can be reversed by weight loss (Kreitschmann-Andermahr et al., 2010). Mechanisms appear to involve direct feedback effects of insulin on the pituitary and a reduction in secretion of the endogenous GH-releasing peptide ghrelin that is produced by the stomach and hypothalamic centers. In addition, although reductions in GH lead to a decrease in hepatic synthesis and serum concentrations of total insulin-like growth factor 1 (IGF-1) in the obese, paradoxically obesity results in a suppression of IGF-binding proteins and thus an increase in free IGF-1. Free IGF-1 can also exert a negative feedback on GH secretion. In addition to effects on the GH–IGF axis, hyperinsulinemia also appears to increase adrenal androgen production and reduce plasma concentrations of sex hormone–binding globulin (SHBG) in obese prepubertal girls (Burt Solorzano and McCartney, 2010). Increased serum concentrations of free androgens appear to explain, in part, why childhood obesity is associated with earlier pubertal development. Rodent studies of high-fat feeding have demonstrated accelerated vaginal opening that was reversed by both androgen receptor blockade and normalization of glucose homeostasis with metformin. Hyperandrogenization also appears to explain the increased incidence of polycystic ovary syndrome (PCOS) in obese adolescent girls with MetS, anovulatory cycles, and subfertility in obese women of childbearing age. Increased adipose tissue mass also results in increased estrogen production as a result of androgen aromatization in fat tissues. This may also contribute to accelerated puberty in girls. Surprisingly, in obese boys, data suggest that puberty may be delayed. This may also be related to increased aromatization of androgens in adipose tissue because negative feedback of estrogens at the level of the hypothalamic–pituitary axis may result in reduced luteinizing hormone secretion and reduced testosterone production (hypogonadotropic hypogonadism). In addition to suppression in GH and gonadotropin secretion, hypothyroidism is common in individuals with MetS. Reduced thyroid hormone concentrations may exacerbate NASH progression in the liver by increasing triglyceride synthesis, reducing fatty acid oxidation, and increasing hepatic cholesterol concentrations by reducing conversion to bile acids (Loria et al., 2009).

Obesity and Cancer Risk

Increased BMI is well known to be associated with significantly increased risk of a number of cancers. These include sex-steroid-dependent endometrial, breast, and prostate cancer, GI tract cancers such as esophageal adenocarcinoma, and colon cancer and renal cancer (Table 28-1). Several mechanisms have been proposed related to endocrine and metabolic disturbances associated with obesity (Roberts et al., 2010). As described earlier, systemic insulin resistance results in hyperinsulinemia and reduces plasma IGF-1-binding protein levels to increase free IGF-1 concentrations. Insulin and IGF-1 signaling interact to stimulate cell proliferation via activation of MAP-kinase cascades resulting in increased phosphorylation of ERK and via activation of Wnt-β-catenin pathways. In addition, they exert antiapoptotic effects through PI-3 kinase pathways. Increased

Table 28-1

Estimated Risk Ratios* for Cancer in Relation to BMI

CANCER TYPE	MEN	WOMEN
Colon cancer	1.24	1.09
Gallbladder cancer	—	1.59
Leukemia	1.08	1.17
Malignant melanoma	1.17	—
Multiple myeloma	1.11	1.11
Esophageal adenocarcinoma	1.52	1.51
Renal cancer	1.24	1.34
Thyroid cancer	1.33	1.14
Prostate cancer	1.03	—
Postmenopausal breast cancer	—	1.12
Endometrial cancer†	—	1.73

**Per increase in BMI by 5 kg/m² (Roberts et al., 2010).*
†For BMIs above 27 kg/m².

sex steroid concentrations in obesity promote growth of tumors in the mammary gland, endometrium, and prostate. Adipokines may also play a role in promotion of obesity-associated cancers. Leptin that is increased as fat mass increases is proproliferative, antiapoptotic, and proinflammatory and promotes new blood vessel formation (angiogenesis). In contrast, adiponectin that is suppressed in obesity has the opposite properties and is inversely associated with the presence of cancer. Additional potential associations between obesity and cancer may involve depletion of cellular antioxidant systems as a result of the low-grade chronic systemic inflammation that accompanies morbid obesity and the possibility that mesenchymal stromal cells arising from expanding white adipose tissue may be recruited to tumors to promote angiogenesis and drive tumor progression (Roberts et al., 2010).

HEALTH BENEFITS AND LIFE EXTENSION ASSOCIATED WITH CALORIC RESTRICTION

The opposite of overfeeding is caloric restriction (CR) (also known as dietary restriction). Over the past two decades, experimental CR has been repeatedly shown to increase life span and reduce age-related disease in comparison with ad libitum feeding in a wide variety of organisms including yeast, nematodes, fruit flies, fish, many rodent species, and dogs (Smith et al., 2010). Recently, Colman et al. (2009) have reported similar findings in rhesus monkeys and a multisite human randomized clinical research study is currently in progress funded by the National Institute on Aging (NIA): Comprehensive Assessment of Long-Term Effects of Reducing Intake of Energy (the CALERIE study, available at: http://calerie.dcri.duke.edu/index.html). Preliminary data suggest replication of many of the results from animal studies, including reduced fat and lean mass; reduced insulin; reduced energy expenditure; lower core body temperature; and improved lipid profiles. It has been suggested that the increased health and longevity associated with CR are related to reduced energy flow, increased insulin sensitivity, and reduced inflammation (Ye and Keller, 2010). Studies in yeast, *Caenorhabditis elegans*, and *Drosophila* have suggested that the life span–enhancing effects of CR are mediated through activation of a family of histone deacetylases known as the sirtuins (Sir), which act as sensors of nutrient flux (Smith et al., 2010). Intensive studies are underway to identify CR mimetics that might have the same benefits as CR on long-term health and longevity without the necessity for imposed food restriction. Most work has focused on the grape polyphenol resveratrol that has been shown to activate Sir2 and to mimic CR effects to increase life span in yeast, *C. elegans*, *Drosophila*, and fish in the absence of nutrient alteration. A second CR mimetic receiving significant attention is rapamycin, an inhibitor of the nutrient signaling mediator target of rapamycin (TOR).

TREATMENT OF OBESITY

Lifestyle Modification: Dieting and Exercise

Attaining a healthy body composition usually requires trimming excess body fat by reductions in total caloric intake, modifications in diet composition, and increases in total energy expenditure (TEE) via increased physical activity. This combined strategy is intended to develop a metabolic state in which energy expenditure exceeds energy intake, and which in turn requires total body energy requirements to come from utilization of body fat stores, thereby burning body fat and improving body composition.

Adhering to almost any commercially available diet plan on the market can achieve body weight loss and reduction of total fat mass. For example, people who use the Atkins diet, which is a diet high in protein and fat and very low in carbohydrates, lose weight. The major problem is sustaining a healthy body composition. Most dieters return to their predieting weight and body composition (or worse) because they never achieve a true lifestyle change that meets their expectations. Comprehensive lifestyle changes that promote sustainability include two major and closely linked components: (1) learning to consume only the number of calories from high-quality foods necessary to support basal body energy requirements, plus energy needs to maintain physical activity; and (2) selecting a reasonable physical activity plan that fits into the dieters' overall lifestyle patterns. Sustaining healthy body composition after significant weight loss seems to occur only in those individuals who can find a way to limit their intake of a healthy diet that they find acceptable in terms of taste, costs, and ease (food availability and ease and speed of preparation), plus an exercise regime that is acceptable in terms of access (e.g., equipment, facilities, and walking trails), appropriateness (e.g., age-related and intensity levels), and time (e.g., duration required and timing within a workday). Thus, losing weight and getting a healthy body composition comes down to energy balance, that is, consuming only enough energy to maintain a given body composition. Maintaining a healthy body composition requires that energy intake equals energy expenditure. Promoting health in the context of a healthy body composition can be best achieved by including a physical activity plan, and this usually leads to healthier muscle, improved insulin sensitivity, normalization of blood lipid profiles, and improved cardiovascular measures.

Determining the energy needs is the easiest part of a plan, whereas limiting caloric intake, increasing physical activity, and sustaining these components of a plan are more difficult. In terms of energy, 3500 cal is stored in 1 lb of fat. So, to lose or take off that pound of fat, the body needs to be forced to "burn" 3500 cal from adipose tissue. That pound of fat was formed over time and under conditions in which calorie intake exceeded caloric output. The energy in food eaten can be "cost accounted" roughly as follows: (1) energy required to digest and absorb food; (2) energy utilized to support basal functions such as pumping blood and breathing; (3) energy for body functions other than basal metabolism, such as walking and playing golf; and (4) nonutilized food calories, such as food components not fully digested or absorbed. Most generally healthy people have similar energy expenditure needs as described in points 1, 2, and 4 above, although there clearly are individual differences. The energy expenditure of a body at rest is termed the basal metabolic rate (BMR) and it can be estimated by the Harris–Benedict equations (Roza and Shizgal, 1984). Energy expenditures also differ by age, gender, and body size (height and weight). For example, per the Harris–Benedict equations, a man and a woman (each healthy and normal body composition) of age 66 years, weighing 160 lb, and 70 in. tall would have a BMR of 1528 and 1372 cal, respectively. However, if they were each age 18 years, their BMR would be 1854 and 1598 cal, respectively. No matter what a person's excess weight might be, there will always be the need for energy to meet the BMR. The energy needs of BMR could be met by diet or, in the case of overweight individuals, body energy stores such as fat. Because there are other nutrient needs besides energy (e.g., nitrogen, amino acids, essential fatty acids, vitamins, minerals, and trace elements), an overweight individual will always have needs for a healthy diet, even for the short term, so fasting is usually not a long-term option to burn all excess stored body fat. Thus, to burn excess body fat, daily energy expenditure needs to exceed the energy expenditure of BMR and this comes mainly from physical activity.

The public tends to overestimate the energy expenditure for various physical activities. It also finds it difficult to practically translate the often-recommended amount of physical activity (30 minutes of activity per day) into a daily regimen. Part of this is due to the difficulty in determining the energy expenditure amount, because the energy expended by an individual on 30 minutes of physical activity differs according to body weight, body composition, health, physical conditioning, the activity itself (e.g., walking, jogging, running, or swimming), and intensity of the activity (e.g., running at 6 mph vs. 4 mph). In addition, many overweight people are usually not accustomed to physical activity at the intensity level and duration needed to induce the body to burn body fat stores that lead to significant body fat reduction. This, when combined with the necessary changes in the diet composition and reductions in caloric intake, makes it difficult to lose body fat and more difficult to maintain a healthy body composition. The most common physical activity used in weight loss programs is walking. Walking 30 minutes at a rate of 4 mi/h for the 160-lb man or woman described above will burn approximately 180 cal. So, if an overweight individual were to maintain the same caloric intake (and same diet) and just increase his or her activity level to 30 minutes of walking at 4 mi/h (a total of 2 mi/day), the calculated fat loss would be 1 lb every 20 days. If he or she also reduced the caloric intake by 180 cal a day and has the same walk schedule, he or she theoretically would reduce the time to lose 1 lb of weight to about 10 days. Thus, the way to reduce body fat (adipose tissue) is to consume less calories than expended (energy deficit) and the rate of fat loss is directly related to the level of the energy deficit (i.e., caloric intake vs. caloric expenditure).

Complicit in any plan to burn body fat stores is that some portion of the total energy expenditure (TEE) must be met by fat stores. This requires a diet intake situation that (1) provides fewer calories than required to meet BMR + any physical activity expenditure; (2) reduces or prevents lipogenesis; and (3) promotes lipolysis. There are several ways and several commercially available diet systems in which this can be accomplished. One of the most widely used diet systems, the Atkins diet, claims to accomplish this by increasing protein (and consequently fat) and limiting carbohydrates.

Following a meal containing an abundance of simple carbohydrates, blood glucose levels rise and glucose gets converted into glycogen by the liver and stored there for future energy use. Maximal glycogen storage is between about 8 and 14 hours, depending on factors such as an individual's metabolism. As glucose enters cells, blood glucose concentrations would fall if not for the liver converting the glycogen back to glucose and releasing it back into the blood. This is a mechanism for maintaining glucose in the normal range between meals. Glucose is the body's energy source of choice. Use of glucose as the primary energy source seems to be prioritized by cell and organ type, with nerve cells having the highest priority. This means that if body glucose stores become scarce, the brain will be the last organ able to use glucose as its primary source. In this case, if another carbohydrate-containing meal is not consumed and blood glucose levels dropped to very low levels, lower priority organs (such as muscle) would need another source of energy and this source is fatty acids released from fat stores (lipolysis). Just like glycogen is the storage form for glucose, fat is the storage source for fatty acids and tissues can easily burn fatty acids when glucose is absent. As liver glycogen stores become minimal, amino acids are converted to glucose (gluconeogenesis). This can support nerve cell metabolism for a while, but eventually the brain will switch from burning pure glucose and start to utilize ketone bodies produced in the liver from fatty acids as an additional energy source. High ketone levels in the blood and tissues are known as ketosis.

Insulin has a major influence on carbohydrate, fat, and protein metabolism. Under conditions of adequate carbohydrate intake, insulin causes excess sugar not utilized as fuel to be stored as fat and prevents utilization of fat as an energy source. Thus, a high-carbohydrate diet. In theory, the low carbohydrate, high protein intake promoted in the Atkins diet forces the body to burn more fat. This would call for the body to switch from using pure carbohydrates for fuel to using more fat for fuel and the source of this fat is the adipose tissue. Thus, when insulin levels are normal, the body will begin to burn its own fat as fuel, thereby resulting in body weight loss. In addition to these potential metabolic effects, the high dietary fat content is thought to reduce appetite and thus total caloric intake. The combination of altered metabolism and reduced caloric intake leads to weight loss and better body composition.

Theoretically, environmental factors (such as diet composition, dietary intake, and physical activity) are the key factors in obesity treatment. However, genetics can also play a major role. For example, Bouchard et al. (1983) have reported that genetic characteristics can be responsible for substantial differences or heterogeneity in the response to training or physical activity and this may be an important obstacle to achieving a healthy body composition in some people. So, although research has shown that obesity can be reversed by the combination of consuming a healthy diet and reducing caloric intake to below calories expended, *maintaining a healthy body composition* with a caloric intake equal to energy expenditure often is as complicated as the factors leading to obesity in the first place.

Clinical and basic research studies have shown that adequate physical activity is essential to maintaining good physical health, and a sedentary lifestyle leads to several common chronic health problems. However, the mechanisms underlying the positive effects of physical activity or the negative effects of insufficient activity are not known. An ongoing NIH study, "Molecular Transducers of Physical Activity in Humans," aims to determine the molecular changes produced by "movement" (i.e., physical activity) and how these changes improve cellular and organ functions (Robinson et al., 2017). Current literature in the field of physical activity as it relates to body composition, health, and disease suggests there is a healthy "fitness range" for individuals based upon genetics and issues such as age, sex, body composition, diet, and total caloric intake. These factors are important in understanding human development, health status, and the effects of medications and toxicants.

Toxic Effects of Dieting

There are potential toxic effects associated with some diet plans. Dieting as prescribed by dieticians, nutritionists, or physicians is based on the use of a healthy diet that meets the daily nutrient needs of the body, but at a reduced caloric intake and with increased moderate physical activity. The overarching premise is to provide adequate nutrients for normal cellular function while reducing caloric intake to a level that forces the use of fat stores as an energy source to meet the energy expenditure above the caloric intake. If the diet does not include all the required nutrients (an imbalanced diet), metabolism will suffer and with time this can result in health problems. This is true in the case of deficiency of specific nutrients (deficiency disorders such as anemia or osteoporosis) or toxicity caused by excesses of a nutrient (such as thyroid impairment, vitamin deficiencies, and mental confusion). Some popular diet plans call for excess intake of a particular food and these can not only alter

metabolism but also interfere with medications. For example, the popular grapefruit diet can lead to inhibition of drug-metabolizing enzymes such as the cytochrome P450 CYP3As that metabolize 60% of all therapeutic medications. This may increase drug concentrations to toxic levels, increase drug–drug interactions, and result in potential health problems (Ameer and Weintraub, 1997; Kiani and Imam, 2007).

Another potential adverse effect of dieting is known as the yo-yo effect or weight cycling. This occurs with repeated dieting interspersed with periods of no dieting. This is caused when a dieter starts one diet and loses a significant amount of body weight and body fat, but cannot maintain the diet and stops to return to the prediet routine. The fat and body weight are regained, often to an even greater body fat content. In fact, the yo-yo experience may result in a condition in which the dieter is more efficient in gaining weight. This causes the dieter to select another diet plan, loss of weight, failure to maintain the diet, and return to overweight or obese conditions. There are often periods of depression and fatigue associated with this cycling behavior and the end results are extreme emotional and physical ramifications.

Drug Therapy for Weight Loss

In addition to the diet plans described earlier, many overweight individuals turn to drug therapy to help lose body weight. Appetite suppressants, for example, sympathomimetics such as diethylpropion, attempt to lessen the psychological motivation for food, usually by acting on central nervous system appetite control centers, such as those in the hypothalamus (Guaraldi et al., 2011). Although sympathomimetics can be used for long periods of time, their appetite-reducing effects tend to decrease after a few weeks in many people. Thus, appetite suppressants are often used in the early stages of a weight loss program. People are likely to lose weight while taking sympathomimetics, but the weight loss is generally temporary without modifications in diet composition, eating behavior, and physical activity. Short-term use is usually accompanied by minor side effects such as thirst, irritability, constipation, stomach pain, dizziness, dryness of mouth, heightened sense of well-being, headache, irritability, nausea, nervousness or restlessness, trembling or shaking, and trouble sleeping. However, long-term use of appetite suppressants often lead to more serious side effects: intracerebral hemorrhage, acute dystonia, myocardial injury, psychosis, cerebral arteritis, cardiac arrhythmias, heart valve damage, and even fatal pulmonary hypertension. These side effects have led to the withdrawal of several such products from the market. Drug interactions are also known to occur, especially with high blood pressure medicine, stimulants, MAO inhibitors (e.g., furazolidone, linezolid, phenelzine, selegiline, and tranylcypromine), any other weight loss medicine, and decongestants such as are commonly found in over-the-counter cough and cold medicines.

Surgical Interventions

Surgery is another avenue to improve body composition in obesity. One of the most radical surgical treatments is the class operations known as bariatric surgeries. The end goal is to limit food intake by reducing the capacity of the stomach, and also having patients feel satiated. Bariatric surgery is a term that includes several surgical procedures (such as sleeve gastrectomy, gastric plication, gastric banding, and gastric bypass surgery); all are aimed at helping obese patients lose weight. Weight loss is achieved by resecting and linking the small intestines to a small stomach pouch (gastric bypass surgery), removal of a portion of the stomach (sleeve gastrectomy), or reducing the size of the stomach with an implanted medical device (gastric banding) or sutures (gastric plication). These procedures are generally credited with significant long-term loss of body fat and body weight, which leads to improvement of secondary conditions caused by obesity, including type 2 diabetes, risk of cardiovascular disease, and the rate of mortality (Robinson, 2009). Very promising preliminary results concerning bariatric surgery bear watching in the future, suggesting the procedure may have effects in a wide range of areas, including changes in the gut microbiome and type 2 diabetes mellitus in nonobese patients (Nguyen and Varela, 2017).

These operations are most commonly used to treat morbid obesity and the comorbidities associated with it. Thus, bariatric surgery may be recommended for people with a BMI greater than 40. These procedures have also been used successfully with obese individuals with BMI 30 to 40, especially when there are serious coexisting medical conditions such as hypertension, impaired glucose tolerance, diabetes mellitus, hyperlipidemia, and obstructive sleep apnea. Most bariatric procedures result in relatively rapid weight loss, which is also associated with gallstones, and many surgeons prefer to remove the gallbladder at the time of bariatric surgery. Malabsorption and nutritional deficiency can occur because of reduced absorptive area. This can reduce calcium and vitamin absorption. Poor calcium absorption can occur because calcium transporters located in areas of the intestine (duodenum) may be removed with bariatric surgery. This can cause metabolic bone disease (osteopenia) and secondary hyperparathyroidism that increase in bone turnover. Combined, these conditions decrease bone mass and increase risk of fracture. Other deficiencies including iron and micronutrients such as vitamin B_{12}, fat-soluble vitamins, thiamine, and folate are common. Many patients will need to take a daily multivitamin pill for life to compensate for reduced absorption of essential nutrients. Because patients cannot eat a large quantity of food, physicians typically recommend a diet that is relatively high in protein and low in fats and alcohol.

Liposuction is another surgical procedure widely used to improve body composition by physically and surgically removing body fat. It is the most common "plastic surgical procedure" in the United States. However, there are significant risks with this procedure and these are mainly associated with (1) the aggressiveness with which the procedure is performed, especially the amount of tissue sucked from the body; (2) the venues in which the procedures are performed; and (3) the amount of anesthesia used to sedate patients during increasingly lengthy procedures. The mortality rate of the late 1990s was approximately 20 per 100,000 or 1 per 5000 cases (de Jong and Grazer, 2001).

ECONOMIC, SOCIOLOGICAL, AND LEGAL ASPECTS OF THE OBESITY EPIDEMIC

Health Insurance and Obesity

Obesity is not considered an illness for most insurance purposes. However, obesity can affect the cost of health insurance because as a group, obese people have a significantly greater risk of cardiovascular disease, hypertension, type 2 diabetes, and other health issues than lean people. Thus, insurance companies factor obesity into the cost of first-time insurance purchasers. Furthermore, people who are already insured may unknowingly not have sufficient insurance to cover health problems associated with obesity. Several health insurance companies use BMI as a measure of obesity and use BMI to compute disease risk and health insurance premiums. Obesity can result in high premiums and in the case of morbidly obese individuals, insurers may decline their application. Obesity is also

regarded by insurance companies as a substantial risk for both life and disability policies.

Mortality statistics for life insurance were the earliest indicator that the cost of obesity to the individual was decreased life span and increased illness, particularly diseases affecting the cardiovascular and musculoskeletal systems. The prevalence of coronary heart disease rises with increases in the BMI in both men and women. Hypertension and diabetes in the obese add further to the risks of vascular disease. Cigarette smoking also greatly augments the health risks of obesity in both sexes.

The risk of death and medical problems increase with the degree or severity of obesity (as indicated by fat mass or BMI). The type of obesity (as indicated by body shape or fat distribution) is another aspect of obesity considered by insurance companies. Abdominal obesity has been positively correlated with the risk of heart disease and stroke. Thus, some insurance companies set rates based in part on fat distribution. Disability insurance rates are also affected by body composition, as cardiovascular disease or musculoskeletal illness associated with obesity greatly increases the chances of disabilities. These factors are used in decision making as to whether to insure an individual and the cost of premiums. Clearly, costs increase proportionally with the degree of obesity.

Changing the Environment: Family and Community Approaches to Healthy Eating and Physical Activity

The development of obesity within an individual, a community, or a country is complex and the central cause(s) or reason(s) underlying the rapid rise in obesity in the United States and the world is not well understood. The end results in terms of body composition and secondary medical problems associated with obesity are better understood than the root causes of the obesity epidemic. One factor, however, that has received much attention relates to basic practices that were common in past decades when the general population was leaner but are lacking now when obesity is so prevalent.

Prior to 1970, the average BMI was 25.1 for men and 24.9 for women in the United States. Physical education (PE) classes were a regular feature of school curriculums; most meals were prepared at home using fresh produce, meats, and dairy products. School lunches were prepared at schools. It was common for children to walk or ride bicycles to school and to participate in games requiring physical activity during school recess and after school and on weekends. There were no computer games and fast food restaurants did not supply such a large proportion of the daily total calories. In the 1990s and 2000s, there are few schools with PE classes and fewer meals cooked from fresh components consumed at home and the lifestyle of today's children and adults is far more sedentary than that prior to 1970. Therefore, by 2002, average BMI for U.S. men had risen to 27.8 and average BMI for U.S. women to 28.1.

One approach to fighting the obesity issue is to bring back many of those practices used in the past. There are initiatives to establish community gardens, build community walking and riding trails, and teach people cooking and shopping skills that lead to healthier meal preparation. School systems are starting to return to PE classes on a regular basis and remove high-density foods and drinks from vending machines. Although these efforts have been increasing in effort throughout the United States, it is still too early to confirm their effectiveness in reversing the obesity trend.

Food security and access to quality foods are an important issue throughout the United States, regardless of whether in rural America or in the inner city. In many areas, there is ready access only to convenience food stores where there is a lack of fresh vegetable and meats and the prices are higher than in a conventional supermarket. The type of food available is poor quality and energy dense, which leads to obesity. These areas have been termed "food deserts." Providing access to higher-quality fresh food to people living in these areas will improve nutrition, and when combined with education on how to select and prepare the food and linked to some form of physical activity it is hoped that body composition and health will improve in these areas.

Food Labels

The Food and Drug Administration (FDA) is responsible for assuring that foods sold in the United States are properly labeled (see Chap. 27, "Food Toxicology: Fundamental and Regulatory Aspects"). This applies to foods produced domestically and foods from foreign countries. The Federal Food, Drug, and Cosmetic Act (FD&C Act) and the Fair Packaging and Labeling Act are the federal laws governing food products under the FDA's jurisdiction. The Nutrition Labeling and Education Act (NLEA), which amended the FD&C Act, requires most foods to bear nutrition labeling. The FDA requires food labels that bear nutrient content claims and certain health messages to comply with specific requirements.

Food labeling is required for most prepared foods, such as breads, cereals, canned and frozen foods, snacks, desserts, and drinks. Nutrition labeling for raw produce (fruits and vegetables) and fish is voluntary. Dietary supplements are a special category of products under the general umbrella of foods, but which has separate labeling requirements. "Functional foods" or "nutraceuticals" are regulated by the FDA under the authority of the FD&C Act, but they are not specifically defined by law. Evidence-based updates of labeling requirements occur when "new data on the associations between nutrients and chronic diseases, health-related conditions, physiological endpoints, and/or maintaining a healthy dietary pattern reflects current public health conditions in the United States." Revisions in the format and appearance of the Nutrition Facts label was last performed in 2016 and full industry-wide compliance with the new regulations must occur by July 2019.

Food labels can be an important factor to help consumers in their food choices that can help prevent obesity and other diseases. Federal law requires that a minimal amount of information be listed on food packaging, including ingredients and nutrition data. The FDA monitors labeling language for such issues as fat, protein, carbohydrate, and other nutrient contents and the purported ability of a particular food to prevent medical problems. Suspicious or doubtful claims or misleading statements about nutrition and health benefits on food packages can be challenged by the FDA and companies that receive warning letters have 15 days to inform the agency of corrective action. Although there has been a formal process by which a health claim can be made, foods generally are not permitted to make disease-fighting claim. The types of claims often challenged by the FDA include warding off maladies such as arthritis, cancer, and heart disease.

The Patient Protection and Affordable Care Act of 2010 establishes requirements for nutrition labeling of standard menu items for chain restaurants, similar retail food establishments, and chain vending machine operators. The most important information that must be provided for standard menu items is the number of calories in each standard menu item and a statement on the menu that puts the calorie information in the context of a recommended total daily caloric intake. In addition to restaurant menus, food sold from vending machines operated by persons who own or operate 20 or more vending machines must disclose the number of calories in a clear and conspicuous manner.

Governmental and Corporate Issues

There has been increasing pressures from local, state, and federal governments to regulate various aspects of food as a means of promoting health and reducing obesity and the secondary consequences of obesity. Food labeling is just one example of government intervention, whereby food processors and restaurants must provide a measure of nutrient and/or caloric content. New York City was the first to pass a law requiring calorie counts to be posted next to prices on menus in some restaurants so consumers would also know the "caloric cost" of each food selection, with the hope that they will make healthy food choices. California became the first state to prohibit restaurants from using "artery-clogging trans fats" in preparing their food. Airlines and the FAA are dealing with complaints from passengers being "infringed on" by overlapping obese passengers and obese passengers complaining about abuse taken from leaner passengers. In an effort to reduce insurance costs and improve work performance, there is also a trend for the business community to set standards associated for overweight and obese workers in a manner similar to that employed for smokers. Civil rights advocates and others are concerned that there is a growing impetus for government intervention and one wonders if the time will come when "big brother" mandates what and how much one can eat.

INTRODUCTION

Since the classic talk by Richard Feynman (1960) entitled "There Is Plenty of Room at the Bottom," nanotechnology has grown to a multibillion dollar industry worldwide, with 1300 nanotechnology-enabled products in commercial use by 2010 (Woodrow Wilson Center, 2012). The potential of adverse effects from exposure to "nanophase materials" was already pointed out earlier (Oberdörster and Ferin, 1992; Oberdörster et al., 1992), and concerns about human and environmental health and safety of engineered nanomaterials (ENMs) were initially raised in 2003 (Colvin, 2003). Since then, toxicity of high volume, commercial nanomaterials including nanosilver, fullerenes, quantum dots, carbon nanotubes (CNTs), graphene-based materials, and metal oxide nanoparticles (NPs) has been summarized in several reviews (Donaldson et al., 2004; Borm et al., 2006; Nel et al., 2006; Boczkowski and Hoet, 2009; Krug and Wick, 2011; Kunzmann et al., 2011; Sanchez et al., 2012). New ENMs and composites are continually emerging with potential for significant commercial applications in energy generation, environmental sensing and remediation, aerospace and defense, and medical diagnosis and therapy. Examples of nanoscale materials of different shapes and sizes are depicted in Fig. 29-1. Investigations of the magnitude of release of manufactured nanomaterials and their subsequent fate, transport, transformation, and potential for human and environmental exposure and toxicity (Fig. 29-2) have been areas of active research (Mueller and Nowack, 2008; Krug, 2014).

The United States National Nanotechnology Initiative (NNI, http://www.nano.gov/) defines nanotechnology as the understanding and control of matter at the nanoscale at dimensions between approximately 1 and 100 nm, where unique phenomena enable novel applications. Roco (2005) defined the sizes as ranging from the intermediate length scale between a single atom or molecule and

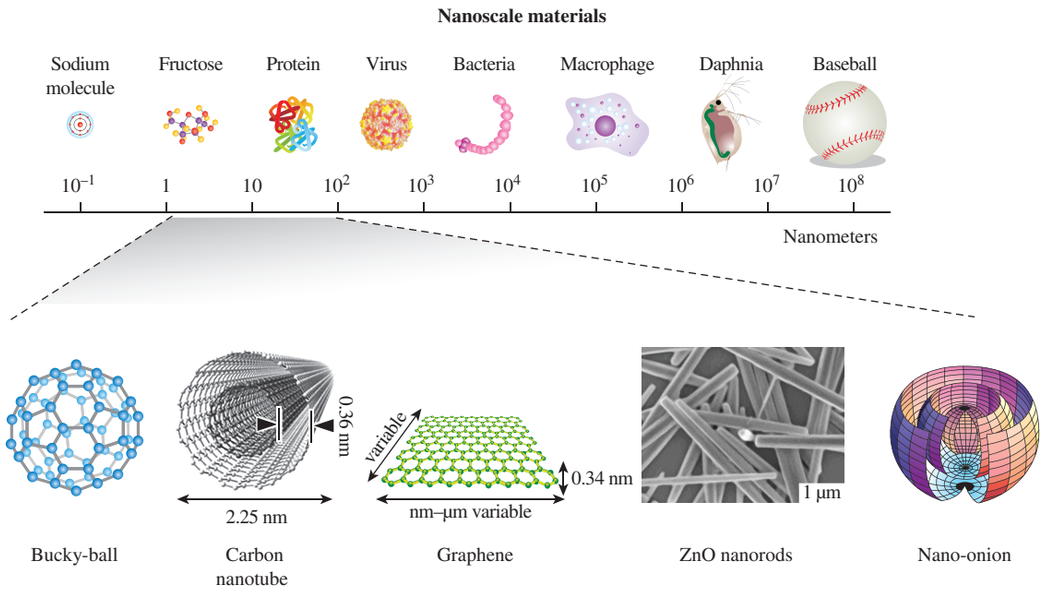

Figure 29-1. *Length scales for natural and synthetic structures (above) and some examples of engineered nanomaterials of varying size and shape (below).*

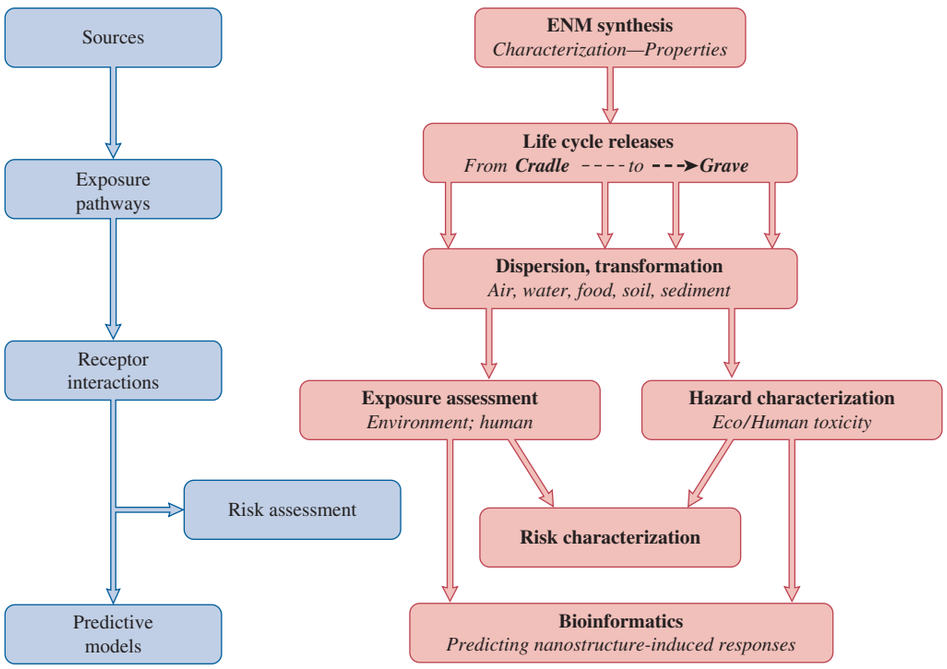

Figure 29-2. *Research phases for assessing human and environmental safety of engineered nanomaterials.*

about 100 molecular diameters or about 100 nm, and emphasizes the ability to measure and transform at this nanoscale and to exploit the properties and functions specific for the nanoscale.

Although the NNI defines nanotechnology as a facilitator of unique properties for novel applications, it is noted that nanomaterials are frequently defined by dimensions alone. For instance, the International Organization for Standardization (ISO) Technical Committee on Nanomaterials (TC 229) defines a nanomaterial as a material with any external dimension in the nanoscale or having an internal structure or surface structure in the nanoscale (ISO/TC, 2015). ISO further describes subsets of nanomaterials and properties resulting from nanomaterials that are nanoenabled and nanoenhanced. These terms emphasize that materials at the nanoscale do not always have dramatically different properties than larger sized materials and that distinctions need to be made between augmented and unique properties. Many material properties may simply be enhanced due to nanoscale size or surface area, whereas a more limited set of properties are uniquely enabled at the nanoscale, for instance, because of quantum confinement effects or the onset of atypical catalytic activity.

SOURCE: From Oberdörster et al. (2007a, 2007b).

Nevertheless, the continuing introduction of nanoscale materials into consumer products, such as TiO_2 in sunscreen creams, antibacterial Ag in textiles, quantum dots in televisions, multiwalled carbon nanotubes (MWCNTs) in sports equipment together with increasing numbers of publications reporting toxic responses mostly observed in in vitro studies, has led to increasing concerns and more public awareness about potential adverse health effects, fostered particularly also by alarmist headlines in the popular press and online media. Unrealistic high doses as well as questionable study designs are most often to blame. Thus, questions should be raised regarding actual versus perceived risk of nanotechnology applications, what is hype, what is reality? To provide answers to these questions is one of the goals of *the subdiscipline of nanotoxicology*.

Nanotoxicology can be defined as the science of studying adverse effects of nanomaterials on living organisms and the environment. As illustrated in Fig. 29-2, there are multiple occasions for exposures to nanomaterials of humans and the environment and there is a serious need for investigation of the potential to cause adverse effects. The need of more toxicological research with the goal of characterizing risks associated with nanotechnology becomes even more urgent when considering the many beneficial and promising applications of nanotechnology for the betterment of human life, also for prophylactic, therapeutic, and diagnostic medical applications. The applications of nanotechnology for human health defines the new field of *nanomedicine*, and the development of new nanoenabled medical technologies must be accompanied by nanotoxicity studies to characterize undesirable effects and ensure the safety of new therapies and medical devices.

The field of nanotoxicology evolved from research on ambient airborne ultrafine particles (UFPs), particles up to about 100 nm in any of three dimensions from diverse anthropogenic and natural emission sources, including tailpipe emissions, power plants, volcanic eruptions, forest fires, and others, as summarized in Table 29-1, which gives examples of three classes: natural NPs, unintentional anthropogenic NPs (or "incidental" NPs), and intentional or engineered anthropogenic NPs. The same toxicological concerns and problems need to be addressed for UFPs and ENMs; they require similar research strategies with respect to study design and characterizing effects and underlying mechanisms at the primary portal of entry and in remote secondary organs. However, not only well-established respiratory tract and air pollution toxicology (see Chaps. 15 and 31) form the basis for nanotoxicology, but findings and knowledge accumulated in other traditional fields of research provide useful complementary information and foundations for nanotoxicology: for example, virology (nanosized structures–cell interactions), metal and polymer-fume toxicology (small particle size and systemic effects), silica toxicology (particle surface reactivity), fiber toxicology (particle shape and biopersistence), radionuclide toxicology (chemistry and biokinetics), and lung deposition studies/modeling (respiratory tract dosimetry) (Oberdörster et al., 2007a, 2007b). Input from these research areas can help in the design of studies and interpretation of results of nanotoxicological research. For example, a major challenge is to correlate the distinct physicochemical characteristics of engineered nanostructures with their toxicological behavior, as will be discussed later.

Of utmost importance for nanotoxicology, as for toxicology in general, are dose-related issues. Administered doses are mostly extraordinarily high when compared to doses achieved in vivo under realistic exposure scenarios. Slikker et al. (2004) stressed that the dose-dependent mechanisms are due to saturation processes underlying toxic responses between typical high acute experimental doses and lower human doses from realistic exposures (Fig. 29-3). Although high doses are justifiable for hazard characterization, ignoring real-world exposure situations may lead to erroneous conclusions about associated risks and causative mechanisms. Thus, consideration of the impact of dose, dose rate (influenced by dosing method in vitro and in vivo), and dosimetry should always be given highest priority when assessing nanomaterial toxicity. Dosimetry involves quantifying or calculating the amount of nanomaterials per body, per organ, per cell (microdosimetry), tissue or airway generation (inhalation route of exposure). Dosimetry should not be confused with "dosemetric," which is defining a dose in terms of an inherent property (physical [number, mass, surface area of ENMs], chemical, reactivity) of nanostructures. Neither should dosimetry or dosemetric be mixed up with "exposure." These issues will be discussed in more detail later.

The goals of nanotoxicology are to identify and characterize a hazard of ENMs for purposes of risk assessment for humans and the environment. This requires a highly multidisciplinary team approach, covering expertise in toxicology, biology, chemistry, physics, material science, geology, exposure assessment, physiological-based pharmacokinetic (PBPK), and fate and transport modeling. Clinical

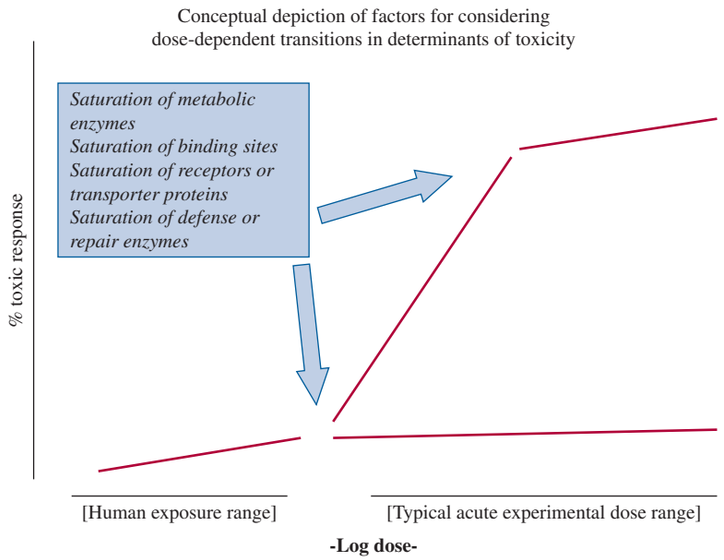

Figure 29-3. *Conceptual depiction of factors for considering dose-dependent transitions in determinants of toxicity.* (From Slikker et al. [2004].)

expertise is also necessary to develop testing strategies, establish toxicity ranking, determine "safe" exposure levels, and derive preventive exposure guidelines. As depicted in Fig. 29-2, exposures throughout the life cycle of ENMs, from their source to their disposal, must be considered. Dispersion state is an important modifier of ENM–receptor interactions, as are physical and chemical transformation of the materials that occur in air, water, food, and soil prior to exposure. Identifying underlying mechanisms of such interactions will aid in assessing risk and establishing preventive measures. Developing predictive models is a distant goal for both human and eco-nanotoxicology.

REGULATORY OVERSIGHT

The uncertainty associated with the potential risks of nanotechnology led the Organization for Economic Co-Operation and Development (OECD) Chemical Committee to establish the Working Party of Manufactured Nanomaterials (WPMN) in 2006. The WPMN remains the leading international forum on regulatory policy and oversight for nanomaterials and addresses issues related to the risk assessment and risk management of nanomaterials regarding human and environmental health and safety. The WPMN comprises international governmental policymakers and subject matter experts including observers from environmental NGOs, unions, UN groups, the International Organization Standardization (ISO), and industry.

In September of 2013, the OECD Council on the Safety Testing and Assessment of Manufactured Nanomaterials recommended that members manage the risks of manufactured nanomaterials, applying the existing international and national chemical regulatory frameworks or other management systems adapted to consider the specific properties of manufactured nanomaterials. It also recommended that in the testing of manufactured nanomaterials, apply the OECD Test Guidelines, adapted as appropriate and in regards to the Mutual Acceptance of Data (MAD) principle in the assessment of chemicals (OECD, 2013).

Member countries have moved forward with the Council Recommendation by integrating nanomaterials into their chemicals regulatory programs. Several jurisdictions have also implemented information collections rules or registries for nanomaterials to acquire information on their prevalence and uses in commerce. However, the application and definition varies largely.

The European Union was the first region to provide a regulatory definition of a nanomaterial in legal text. The European Commission's (EC) Recommended Definition of a Nanomaterial defined nanomaterial as "a natural incidental or manufactured material containing particles, in an unbound state or as an aggregate or an agglomerate and where, for 50% or more of the particles in the number size distribution, one or more external dimensions is in the size range 1 nm–100 nm" (European Commission, 2011a, 2011b). Because some traditional nanomaterials are less than 1 nm, it was clarified that fullerenes (a form of carbon containing a large spheroidal molecular consisting of a hollow cage of atoms); graphene flakes (free-standing flake consisting of small number of well-defined, stacked graphene layers of extended lateral dimension); and single-walled carbon nanotubes (SWCNTs—having a diameter close to 1 nm with a tube length many times longer) with minimum dimensions below 1 nm are considered by derogation. This definition faced technical hurdles from the start as robust methods for determining number percent distributions of nanomaterials derived from bulk powders and suspensions were not in place (Linsinger et al., 2012; Brown et al., 2013; Amenta et al., 2014; Rauscher et al., 2014, 2015). The number percent metric was also criticized since at 50% by number, the larger sized populations of particles would contribute the most surface area, and potentially the dominant contribution to effects. Fig. 29-4 provides an illustration of the difference between a number percent and a mass or volume percent metric and demonstrates the surface area discrepancy. A revision to this definition is anticipated in late 2018 or in 2019 with accompanying guidance documentation.

Despite uncertain metrology, soon after the release of the EC recommended definition, several countries within Europe began national inventories and reporting rules borrowing aspects of the EC recommended definition of a nanomaterial. This was implemented to avoid capturing specific classes of materials based on applications, potential for release, or incidental production. France,

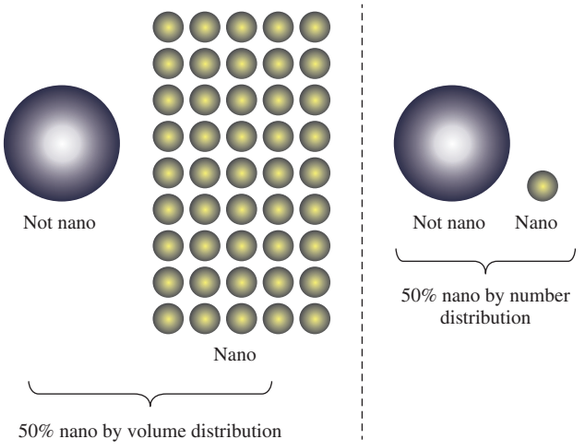

Figure 29-4. *Schematic illustration of the differences between volume and number distribution.* (Reproduced from Brown et al. [2013].)

Belgium, Denmark, and Norway require the reporting of nanomaterials or articles containing nanomaterials. The EC developed a nano-observatory in 2017, for public outreach and information sharing on nanomaterials in commerce. Outside of Europe, both Canada and the United States have also moved forward with reporting rules; however, unlike Europe they did not choose to move forward with a regulatory definition. Other regions of the world are following suit including Taiwan and South Korea.

The regulatory actions that have taken place to date are largely monitoring activities, in part due to marked uncertainty in the sciences as well as the uses, quantities, and diversity of nanomaterials in commerce. After over a decade of research, the vast body of the scientific literature remains questionable. Publishing bias and poor quality research are significant concerns further complicated by increasing information accessibility to the public. Claims of potential adverse effects continue to influence public perception despite related concerns of research quality and human relevance. A large fraction of nanotoxicology research fails to meet basic levels of scientific rigor and reporting (Krug, 2014). The preferential use of non-guideline methods and the reluctance of scientific journals to accept "no effects data" remain concerns hindering a balanced outlook (Warheit and Donner, 2015).

Early outputs from national commercial nanomaterial monitoring efforts indicate that the largest application of nanosized materials are for coatings and inks that have safely been used in commerce for decades. The identification of these applications largely results from the scope of the definitions applied in those reporting efforts being simply focused on the size of the relevant constituent particles. The US EPA's Section 8A rule notably sets a precedent and narrows the reporting requirement to nanoscale materials possessing unique and novel properties while applying a mass percent cutoff including agglomerates and aggregates. These criteria significantly narrow the scope of materials and possess far fewer metrology challenges.

NANOMATERIAL BASICS

Perspectives: Engineered Nanoparticles versus Ambient Particulate Matter

A large body of publications on the toxicology of airborne ambient particulate matter (PM) has shown that they can elicit adverse effects not only in the respiratory tract but also in secondary organs and systemically (see Chap. 31 on Air Pollution). An extensive critical review of the health effects of fine particulate air pollution (Pope and Dockery, 2006) pointed out that exposure to the smallest fraction of PM, referred to as UFPs or $PM_{0.1}$, particles smaller than 0.1 μm or 100 nm, has been associated with effects in the cardiovascular and central nervous system as a consequence of their translocation to and distribution via blood circulation and neurons. It is noteworthy that the definition of UFPs is based on the same maximum dimension (100 nm) as the US NNI and ISO/TC 229 (2015) definition of nanomaterials. As will be discussed later, translocation of UFP and engineered nanoparticles (ENPs) has been clearly demonstrated, but only small amounts are translocating, and thus direct interaction of the translocated particles with organs beyond the lung may not be the sole explanation for their effects. Epidemiological studies have demonstrated that a major factor for inducing adverse effects from ambient particulate air pollution—including UFP—is susceptibility such as pre-existing disease (asthma, cardiovascular disease, diabetes), age (very young, elderly), or genetic background (polymorphism).

A recent comprehensive review assesses and compares epidemiological and toxicological research of ambient UFP versus ENM (Stone et al., 2017). Effects and underlying mechanisms of cardiovascular, CNS, and other organs targeted by inhalation exposures to both types of particles are described, summarized by a workshop of experts who identified 19 lessons which are meant to facilitate knowledge exchange between different disciplines. Gaps in a number of key areas are identified where additional research will facilitate simultaneously both the ambient and engineered nanoparticle research. The authors point out the opportunity to apply knowledge from ENM toxicology to inform ambient PM health risk research and vice versa.

Properties and Behaviors of ENPs versus Larger Particles

Table 29-2 contrasts differences between NPs (<100 nm) and larger particles (>500 nm) in terms of some general characteristics, translocation propensity, interactions with cells, and effects, assuming inhalation exposure and the respiratory tract as the portal of entry. Biological systems do not perceive a precise boundary at the 100 nm size threshold, but rather a gradual transition between nano- and larger-sized particles, and therefore, the 100 to 500 nm size is shown but not covered in the table. Particle scientists tend to refer to this transition zone as the intermediate zone between particle size scale dominated by surface interactions (smaller particles) and size scales predominantly dominated by gravity or internal interactions (larger particles). The general phenomena explain why granular sugar readily flows like a liquid when poured but fine powdered sugar and flour do not. This is also the same consideration that explains why nanoscale particles can form dispersions that do not settle unlike coarser materials. For a variety of reasons, the range of 0 to 100 was used; however, the applicable transition size range depends on the particle shape, density, and other system factors that are beyond the scope of this chapter and not covered in the table.

Marked differences—which will be discussed in the following sections—between the smaller and larger size classes are as follows: The high number and surface area per unit volume of NPs, which enhance the chemical reactivity (e.g., as catalysts) of small particles and potentially increase their biological/toxicological activity toward cells and tissues; the underlying mechanisms for deposition of inhaled particles in the respiratory tract, which is governed by diffusion or Brownian motion for NP versus sedimentation, impaction, and interception for larger particles; and differences

Table 29-2

What Is Different: Nanoparticles versus Larger Particles (*respiratory tract as portal-of-entry*)

	NANOPARTICLES (<100 nm)	LARGER PARTICLES (>500 nm)
General characteristics		
Ratio: number or surface area/volume or mass	High	Low
Agglomeration in air, liquids	Likely (dependent on medium and surface)	Less likely
Deposition mechanism in respiratory tract	Diffusion; throughout resp. tract	Sedimentation, impaction, interception; throughout resp. tract
Protein/lipid adsorption in vitro	Very effective and important	Less effective
Protein/lipid adsorption in vivo	Yes	Some
Translocation to secondary target organs	Yes	Generally not (to liver under "overload")
Clearance		
• Mucociliary	Probably yes	Efficient
• By alveolar macrophages	Poor	Efficient
• Into or across lung epithelium	Yes	Mainly under overload
• Lymphatic	Yes	Under overload
• Blood circulation	Yes	Under overload
• Sensory neurons (uptake + transport)	Yes	Not likely
Cell entry/uptake	Yes (caveolae; clathrin; lipid rafts; diffusion)	Yes (primarily phagocytic cells)
• Mitochondria	Yes	No
• Nucleus	Yes (<40 nm)	No
Effects (*caveat: dose!*)		
At secondary target organs	Yes	(No)
At portal of entry (resp. tract)	Yes	Yes
• Inflammation	Yes	Yes
• Oxidative stress	Yes	Yes
• Activation of signaling pathways	Yes	Yes
• Genotoxicity, carcinogenicity	Probably yes	Some

with regard to the extent and impact of adsorptions and adsorbed conformation/activity of proteins and lipids (corona formation) for larger versus smaller particles at the primary portal of entry and secondary target sites.

Mucociliary and alveolar macrophage-mediated elimination following deposition in the respiratory tract is efficient for both nano- and larger particles once they are internalized by macrophages. NPs inhaled and deposited as singlets, however, are too small to be efficiently recognized and phagocytized by alveolar macrophages (Oberdörster et al., 2005; Semmler-Behnke et al., 2007; Geiser et al., 2008)—unless they are aggregated or agglomerated to form larger particles—and thus overall alveolar macrophage-mediated clearance in the lung is poor. In contrast, uptake by epithelial cells and translocation into blood and lymphatic circulation occurs regularly for NPs, and only under heavy overload conditions for larger particles. Uptake of nanosized particles into sensory nerve endings of the tracheobronchial tree has also been described (Hunter and Undem, 1999), which is unlikely to occur for large particles.

Differences in cell entry mechanisms between NPs and larger particles and intracellular distribution to mitochondria and the nucleus are discussed in subsequent sections. With regard to the type of effects induced at the primary site of entry, there does not seem to be a fundamental difference. However, effects in secondary organs are more likely to develop, possibly aided by a direct effect of translocated NP.

Manufactured NPs show a range of other size-dependent properties and behaviors. Among these are nanoenabled properties such as depressed melting points, size-dependent electronic band gaps, quantum mechanical effects giving rise to size-tunable fluorescence in quantum dots (semiconductor NPs), and confined plasmon resonance, which shifts the light absorption and scattering in a way that alters the colors of nanoscale materials from their larger-sized counterparts, giving rise—for example—to nanosilver particles that appear yellow and to gold NPs that appear red. Unique size-dependent properties of NPs form the basis for many of their technological uses, but the significance of many of these properties for biological effects still needs to be evaluated.

Classes of ENMs

Manufactured nanomaterials cover an enormous range of chemical compositions, and geometries, ranging from simple isometric forms (particles), one-dimensional (1D) forms (nanofibers, tubes, rods, wires), and two-dimensional (2D) forms (plate-like or disk-like materials typically referred to as "nanosheets," for very thin and flexible forms, or "nanoplatelets" for thicker stiff materials). A large fraction of the stable elements in the periodic table have now been cast into NP forms, or incorporated as part of a nanocomposite structure. Nanomaterials can be manufactured from metals, metal oxides, sulfides or selenides, carbon, polymers, or from biological molecules including lipids, carbohydrates, peptides, proteins, and nucleic acid oligomers. Fig. 29-5 presents a nanomaterial classification system based on a matrix involving geometry (particles, 1D forms, 2D forms) and chemistry (metals, semiconductors, ceramics, carbons, polymers; Duncan, 2011; Cassee et al., 2011; Feng and Liu, 2011; Rosenthal et al., 2011; Tran and Nguyen, 2011). The combination of geometry and chemistry gives rise to a vast

Chemistry \ Geometry	Isometric particles	1D; fibers/tubes	2D; plates, disks
Metals	Silver, gold nanoparticles Iron, cobalt, nickel magnetic NPs Copper NP conducting inks	Gold or platinum nanowires	Silver nanoplates
Semiconductors	CdSe/ZnS quantum dots (see example)	Si, ZnO semiconducting nanowires, nanorods	Plate-like semiconductor nanocrystals
Ceramics	Zinc oxide, titanium dioxide pigments and sun screens, cerium oxide catalysts	Electrospun ceramic nanofibers for composite fillers	Nanoclays MoS_2 nanosheets h-BN nanosheets
Carbons	Fullerenes, carbon black, carbon nanohorns	Carbon nanotubes Carbon nanofibers	Graphene, graphene oxide few-layer graphene (example)
Polymers	Biodegradable polymer nanobeads for medical applications, branched dendrimers	Electrospun polymer nanofibers	
Examples:		 Single-walled carbon nanotube	 Graphene

Figure 29-5. *Classification of nanomaterials by geometry and chemistry.* The examples in this matrix illustrate the diversity in engineered nanomaterials, a diversity that continues to increase as new nanomaterials are synthesized.

number of potential nanomaterials. Not all are, or will be commercially significant and find widespread use, but a great many have been synthesized and characterized in R&D laboratories around the world. Nanomaterials may be adhered to surfaces such as biomedical implants to enhance their function and biocompatibility, or incorporated into nanostructured solids or composites to improve strength, conductivity, and durability. Nanomaterials are often integrated into complex, active structures for chemical or biological sensors or other devices.

There are many approaches for synthesizing and manufacturing nanomaterials. Some methods use high-temperature processing in the vapor phase, such as inert gas condensation, flame synthesis, or "floating catalyst" chemical vapor deposition (Zhang et al., 2011). These processes produce dry powders that can lead to occupational exposures when reactors are opened to extract products or the powdered materials are handled or transferred. Other methods such as physical or chemical vapor deposition grow nanostructures on substrates. Substrate-bound nanostructures are less likely to cause exposures of concern, but can become detached during processing or use. A large class of methods uses solution processing, also known as "colloidal synthesis" (Tran and Nguyen, 2011). These methods involve reagent addition to liquid solvents to nucleate NPs that remain suspended in the liquid. This class of methods is less likely to lead to inhalation exposures, but they can occur if the liquid is sprayed or nebulized to produce mists, or if the NPs are dried into powders or transferred onto substrates and dried for further processing (Hallock et al., 2009).

Finally, most nanotoxicology research has focused on a limited set of simple nanomaterials with high manufacturing volume or the potential for high manufacturing volume in the near term

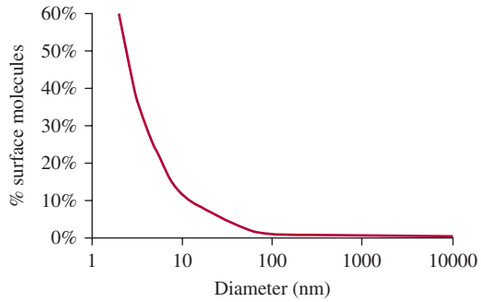

Figure 29-6. *Fraction of molecules in a particle that lie on its surface as a function of particle size.* (From Fissan [2008].)

(including ZnO, TiO_2, fullerenes, CNTs, nanosilver, quantum dots). Increasingly, the nanotoxicology field will have to focus on more complex nanomaterials under development, especially as technological applications for those materials approach commercialization (Maynard et al., 2011). It will be a major challenge for the nanotoxicology field to acquire the data necessary for risk assessment on the many new nanoproducts that are anticipated over the coming decades. Finally, as nanoscience progresses, there will be less emphasis on simple geometries and chemistry (see Fig. 29-6) and more emphasis on complex material structures that combine nanoelements into active or smart structures (Dvir et al., 2011). Early examples of this are the synthesis of two-component or "dumbbell-shaped" NPs composed of gold and iron oxide (Xu et al., 2008) or iron–platinum nanowires (Wang et al., 2007).

Understanding the toxicological profile of complex nanoassemblies will also present a major challenge to the field in the future.

The classification and categorization of nanomaterials for regulatory purposes has proven to be a challenge. Several expert workshops on grouping and categorization of nanomaterials have been conducted. In general, it is concluded that at present nanomaterials need to be considered on a case by case basis, applying information from bulk chemistry, surface chemistry, and shape. The increasing complexity of ENM design involving components from various material classes (e.g., metals, polymers, and metal oxides) integrated in increasingly intricate structural assemblies further challenges universal read-across and categorization schemes.

Physicochemical Properties of Nanomaterials Relevant for Toxicity

For chemical substances existing as liquids or gases, physicochemical frameworks exist for predicting exposure, biopersistence, and for screening potential toxicological consequences primarily through phase partitioning behavior (e.g., water solubility, octanol-water partitioning, vapor pressure, boiling and melting point [USEPA, 1997]). For finely divided solid particulate materials the evaluation becomes more complex. While multi-micrometer-sized particles may have little potential for migration or exposure, nanosized materials share attributes from both larger particles and molecules that draw concerns. Some ENMs can exhibit prolonged dispersion and Brownian motion like molecular solutes; however, they also have solid surfaces that are susceptible to hydration, ionization, adsorption, and transformation process. The later results in the stability and compartmental behavior of ENMs being largely dependent on environmental factors and history. The transport behavior of nanomaterials tends to be extrinsic, stochastic, and relatively irreversible in nature. Moreover, for extremely small nanomaterials (e.g., on the order of 10 nm) traditional, intrinsic, physical–chemical properties such as conductivity and light adsorption can become extrinsic in nature and dependent on interactions with molecules in the environment among other systemic factors. These unique attributes give rise to the use of ENMs for sensing applications, but further complicate their characterization and categorization as chemical substances.

Fig. 29-7 summarizes the nanomaterial properties known or thought to be relevant to biological responses. These properties are discussed in more detail in the section below, or in some cases in later sections on mammalian toxicity and ecotoxicity.

Particle Size, Distributions, Geometry, and Dimensions

Nanomaterials exist as populations of particles with variations in dimensions and morphology. The distribution of sizes and shapes impacts transport and exposure phenomena and can influence cellular uptake. Particle size, although used to define nanomaterials, is not an intrinsic property and can change substantially in the environment through dissolution, precipitation, agglomeration, and heteroagglomeration processes. Agglomeration is the process wherein two or more similar particles weakly stick to one another through physical interactions. Heteroagglomeration is the process where particles of different compositions similarly form weak associations. Monitoring and predicting particle size distributions under real exposure scenarios can be challenging, and typically only size distributions thought to be characteristics of the nanomaterial at key times are reported (e.g., as prepared, as delivered). For biomedical applications, nanoparticles of narrow size distributions are typically desired for consistent delivery or excretion. Dispersed particles in the circulation less than 5 nm are cleared via renal excretion, particles less than 50 nm are excreted via the hepatobiliary route.

The geometry and dimensions of nanomaterials are also important in cellular uptake, systemic translocation, potential

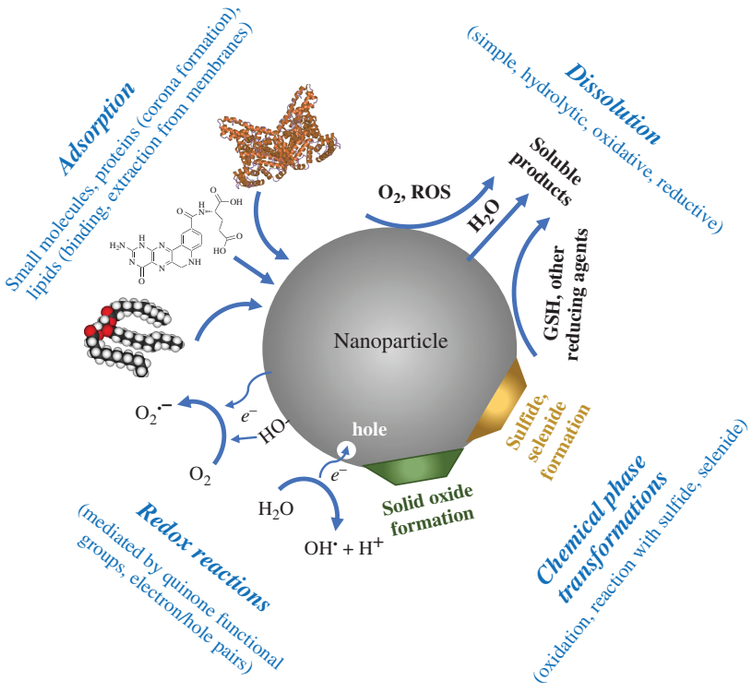

Figure 29-7. *Physicochemical and functional NP properties of relevance for toxicology.* (From Robert Hurt [2018].)

toxicity, and excretion. Nanomaterials can enter target cells by passive diffusion, direct physical penetration, or active, receptor-mediated uptake by endocytosis or phagocytosis depending on their size and extent of agglomeration. For example, small NPs up to 50 nm in diameter appear to enter cells and subcellular organelles, including mitochondria and the nucleus, by passive diffusion (Geiser et al., 2005; Chithrani, 2010). SWCNTs have been shown to directly puncture bacterial cells leading to osmotic lysis and death (Kang et al., 2007; Akhavan and Ghaderi, 2010). SWCNT have been reported to translocate from the alveoli into the interstitium of the lung where they promote collagen deposition and interstitial fibrosis (Wang et al., 2011a). Rigid, long, high-aspect ratio (needle-like) nanomaterials, similar to amphibole asbestos fibers (Palomaki et al., 2011), are recognized by macrophages; however, they undergo incomplete uptake or frustrated phagocytosis if they are longer than the macrophage diameter (Shi et al., 2011), resulting in impaired clearance from the lung, lysosomal disruption, and activation of the inflammasome resulting in the release of pro-inflammatory cytokines (Hamilton et al., 2009; Donaldson et al., 2010). High-aspect ratio materials (i.e., particulates with significantly greater lengths relative to diameters—e.g., fibers) with 2D structure (nanosheets) also show geometry-dependent cellular interactions. These include spontaneous cell membrane penetration initiated at near-atomically thin edges and corners of the 2D sheets (Li et al., 2013), or for nanosheets with large lateral dimension, impaired macrophage uptake (Sanchez et al. 2012), and lung injury at high doses (Roberts et al., 2016).

Surface Charge, Steric Interactions, and Agglomeration

NPs have a strong tendency to form agglomerates in the dry state, and in many cases also in liquid suspension (Fig. 29-8). This tendency is a natural consequence of small size, which leads to intermolecular attractive forces that are strong relative to gravity or to other forces that disrupt aggregates. Attractive forces between particles are determined by size, density, chemistry, electronic structure, morphology, and surface charge. In water, van der Waals forces and hydrophobic forces drive the agglomeration of many NP types. To obtain stable dispersions of non-agglomerated nanomaterials, it is typically necessary to add macromolecular coatings (*caveat*: by doing so it will change particle property potentially affecting toxicity) that prevent particle–particle attachment through steric hindrance, or to impart an electrical charge on the NP surfaces that lead to particle–particle repulsion. A common indicator of surface charge is the "zeta potential" which is the electrical potential at the outer surface of the liquid shell (including, adsorbates, ions, solutes, and solvent molecules) that travels with the particle during its motion. A common rule of thumb is that the zeta potential must be >30 mV or <-30 mV for repulsion to be sufficiently strong to avoid agglomeration and maintain a uniform dispersion. In physiological fluids or seawater, sodium chloride and other ions "screen" the particle surface charge and lower the zeta potential, often causing aggregation. This property is a complicating factor in nanotoxicology assays (discussed below) and is a challenge for some biomedical applications. NPs may also adsorb molecules from their environment that *increase* stability (Nel et al., 2009). Following injection or inhalation, NPs become coated with biomolecules such as serum albumin, an amphiphilic protein that carries poorly soluble molecules in the blood, or phospholipids in lung surfactant lining the alveoli as discussed in detail subsequently. For drug delivery applications (De Jong and Borm, 2008), NPs may be coated with biocompatible surfactants such as sodium cholate, or by biocompatible polymers such as phospholipid-polyethylene glycol (PEG) that stabilize colloidal suspensions of NPs through steric hindrance—a mechanism separate from electrostatic repulsion as indicated by zeta potential.

Surface Area and Reactivity At the nanoscale, chemical and physical forces govern the assembly of atoms or molecules resulting

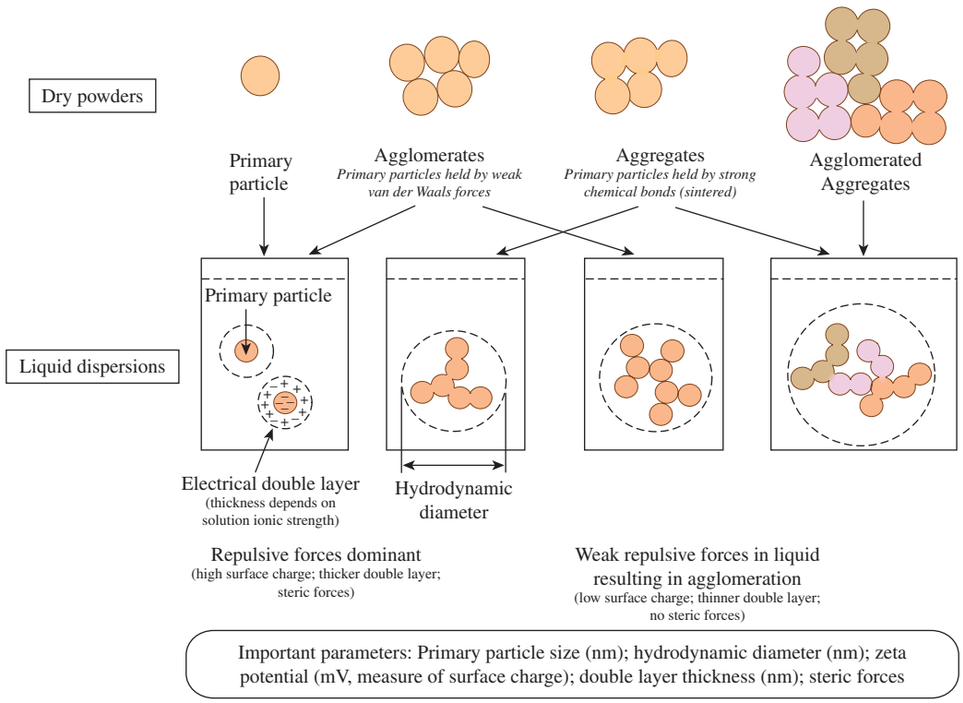

Figure 29-8. *Agglomeration and aggregation of nanoparticles in liquids and as dry powders.* (Modified from Jiang et al. [2009].)

in nanostructures with a high surface-to-volume or surface-to-mass ratio. For example, 5 nm spherical NPs have 1000 times the surface area of 5 μm particles of the same chemical composition and at the same airborne mass concentration. This high surface area of suspended NPs at equivalent mass concentrations is responsible for increased surface reactivity, increased adsorption of chemicals, strong catalytic activity (on an equivalent mass basis), and enhanced dissolution rates. As particle diameter decreases below ~100 nm, the number of exposed surface molecules increases sharply (Fig. 29-9; Oberdörster et al., 2005). The large number of exposed surface molecules or atoms exposes surface defects, vacant sites, and dangling chemical bonds that enhance chemical and redox reactivity. Thus, the NP surface can have higher surface area, higher surface energy (e.g., through surface curvature), and higher surface reactivity relative to the same mass of micron-sized particles of the same chemical composition (Fenoglio et al., 2011). Determining specific surface reactivity—e.g., ROS generating capacity per unit NP surface area—has been suggested as a measure to group ENMs (Oberdörster and Kuhlbusch, 2018).

Surface Chemistry, Surface Morphology, and Surface Impurities The surface chemistry of NPs strongly influences the mode and type of interactions with biotic systems. High surface area, high surface curvature, and exposed surface atoms or molecules promote increased dissolution and release of ions from metallic or metal oxide NPs relative to bulk particles of the same chemical composition in fluids. As an example, Ag^+ ions can be slowly released from nanosilver particles in aqueous environments through oxidation by dissolved O_2 (Liu and Hurt, 2010). This ion release accounts for much of the bactericidal properties of clothes, toys, and medical devices coated or impregnated with nanosilver particles. Metal ions are toxic to bacteria and aquatic organisms by inhibition of enzymes and transport proteins. Silver ions have been shown to induce swelling of the lamellae of trout gills due to inhibition of carbonic anhydrase and Na^+/K^+ ATPase activity (Scown et al., 2010). ZnO NPs are incorporated into sunscreens where they absorb ultraviolet (UV) light; however, in water, Zn^{2+} ions are rapidly released and cause acute toxicity (Xia et al., 2008a). Surface hydrophilicity of charged NPs increases their ability to be suspended in water, whereas surface hydrophobicity of fullerenes or graphene repels water and enables these hydrophobic nanomaterials to partition into lipid membranes and gain entry into target cell (Sayes et al., 2005; Titov et al., 2010). TiO_2 NPs are used in sunscreens because they absorb UV radiation, but their small size reduces the scattering of visible light, and the sunscreens appear transparent to the human eye. UV absorption can also lead to formation of electron/hole pairs that react on the particle surface to generate reactive oxygen species (ROS) such as superoxide anion (O_2^-) from molecular oxygen (O_2) (Schilling et al., 2010). Surface defects, especially on crystalline NPs, expose electron donor/acceptor active groups that donate an electron to molecular oxygen, generating superoxide anions, or accept electrons from water producing the highly reactive hydroxyl radical. Spontaneous or photoactivated generation of electrons can occur based on the semiconducting properties of fullerenes and some metal oxide NPs (Xia et al., 2006).

Industrial nanomaterials are synthesized through a wide range of chemical processes and are purified to differing degrees. It is not uncommon to receive nanomaterials that contain residual surfactants, ions, acids, bases, and other potential reaction contaminants. Due diligence is required to determine whether these residual materials are key contributors to observed outcomes.

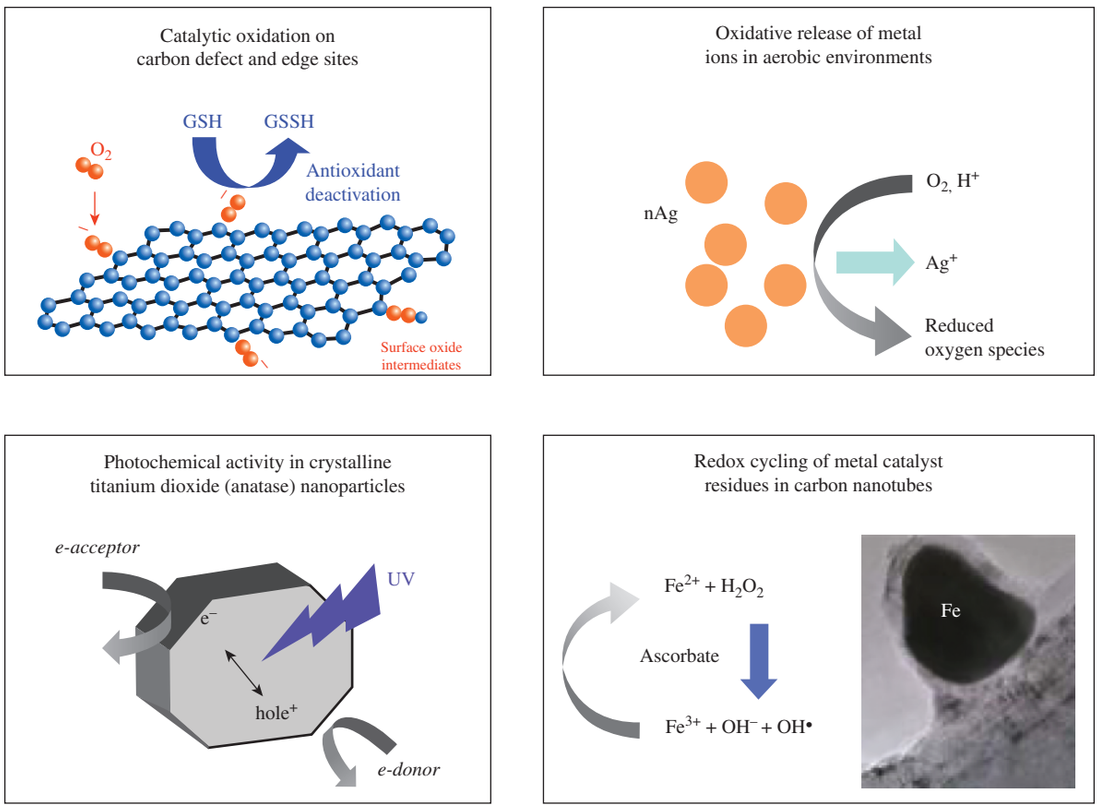

Figure 29-9. *Examples of biological reactivity of nanoparticles.*

For instance, CNTs are synthesized in the presence of metal catalysts, usually iron, nickel, or cobalt, and may contain redox-active metal residues that can undergo redox cycling and iron-catalyzed generation of highly reactive hydroxyl radical ($OH^{\bullet}$) via Fenton chemistry (Kagan et al., 2006; Guo et al., 2007). The high surface area of ENMs can adsorb organic molecules such as polycyclic aromatic hydrocarbons that are potentially carcinogenic (Yang et al., 2006) and quinones that also participate in redox cycling and generation of free radicals (Nel et al., 2006). Cationic NPs that have surface amide groups and cationic dendrimers are especially cytotoxic because they induce membrane damage, especially in lysosomes where the "proton sponge effect" leads to accumulation of water and chloride ions and osmotic rupture (Xia et al., 2008b).

In summary, surface properties are major determinants of biological reactivity due to (1) high surface area, (2) surface charge, (3) hydrophobicity and partitioning into lipid membranes, (4) dissolution and release of metal ions, and (5) redox activity leading to generation of ROS (Nel et al., 2006, 2009; Xia et al., 2008b; Stone et al., 2009).

Unique Properties NPs also have the potential to display unique electronic and magnetic properties relative to micron-sized particles. NPs may interact with energy differently from larger sized materials due to changes in electronic structure, and increasing dominance of surface versus bulk contributions to properties making parameters, commonly thought of as being intrinsically a function of environment. As previously mentioned, it is this surface sensitivity that gives rise to the use of nanomaterials as sensors (e.g., metal-oxide semiconductor field-effect transistors) in a wide range of potential applications. The small size and shape of nanomaterials can also lead to changes in electronic structure that in turn impacts how the nanomaterial interacts with electromagnetic energy. For example, noble metal NPs show preferred wavelengths for absorption and scattering of light due to resonant electron oscillations. This "confined plasmon resonance" phenomenon is shown by 40 to 100 nm diameter gold or silver NPs and leads to color shifts that impart a yellow color to nanosilver and a red color to some types of nanogold (Tran and Nguyen, 2011). Ferromagnetic NPs (e.g., iron, nickel, cobalt, and some oxides) less than about 10 nm in diameter exhibit the property of superparamagnetism. These particles respond strongly to an external magnetic field but have no permanent magnetic moment in the absence of the field because thermal energy is sufficient to cause fluctuations in the small magnetic dipole associated with each particle (Cole et al., 2011). This property is exploited for contrast enhancement in diagnostic MRI and for hyperthermia induced by an external magnetic field to kill tumors targeted by magnetic NPs (Fortin et al., 2007). Although these properties are evident for some nanomaterials, unique properties—distinct from larger sized forms of the material—do not automatically appear with the scaling of size.

Biopersistence Biopersistence of ENMs is an important factor in their environmental and biological toxicity. Biopersistence is determined by mechanical clearance and dissolution processes; the latter not only produces biologically active soluble species (as discussed above), but can also degrade the particle and eventually clear it from biological tissues. ZnO NPs are an excellent example of an ENM that can exhibit acute cellular toxicity due to rapid release of Zn^{2+} ions. The rate of dissolution of metal oxides is increased by natural organic matter in the aqueous environment (Xia et al., 2008b); therefore, these NPs have low biodurability and it is predicted that they would not bioaccumulate in the environment. Following uptake by macrophages at the site of entry, metallic and metal oxide NPs reach the acidic phagolysosomal compartment where release of metal ions is accelerated. Intracellular release of Zn^{2+} or Ni^{2+} ions, for example, is linked with significant acute toxicity to target cells in the lungs (Liu et al., 2007; Xia et al., 2008b; Pietruska et al., 2011). Even metallic nickel NPs which are insoluble can undergo oxidation by O_2 following exposure to produce soluble surface oxides. This slow oxidation dissolution process produces sustained intracellular release of Ni^{2+} ions that cause persistent inflammation (Lu et al., 2009) and activation of the HIF1-α signaling pathway in human lung epithelial cells (Pietruska et al., 2011), which has been linked to nickel carcinogenicity (Costa et al., 2005). Jakubek et al. (2009) reported that release of yttrium ions in trace levels from CNTs displaces Ca^{2+} from voltage-gated calcium channels with implications for neuronal activity. So far, no chronic rodent carcinogenicity assays have been conducted to assess whether inhalation of metal or metal oxide NPs can induce lung cancer or neurological disease.

In contrast, carbon nanomaterials are not easily oxidized under most environmental conditions. They are potentially biodurable, raising concern that they could bioaccumulate in the environment or be biopersistent in the lungs and other organs following inhalation during occupational exposure or direct injection or implantation in biomedical applications (Bianco et al., 2011). Some commercial types of long, rigid, high aspect ratio CNTs have been shown to induce toxicological endpoints similar to carcinogenic asbestos fibers (Sanchez et al., 2009) as discussed in detail below. Biopersistence in the lungs and pleural or peritoneal spaces is an important physicochemical characteristic of asbestos and man-made mineral fibers associated with carcinogenicity (Bernstein et al., 2005). Several recent studies have shown that carboxylated SWCNTs undergo oxidative degradation in the presence of the plant enzyme, horseradish peroxidase, and H_2O_2 (Allen et al., 2008, 2009), or following exposure to phagolysosomal simulant fluid containing H_2O_2 to mimic the lysosomal compartment of macrophages (Liu et al., 2010c). Oxidized or nitrogen-doped MWCNTs also showed both exfoliation of the concentric tubes and shortening in the presence of horseradish peroxidase and H_2O_2 (Zhao et al., 2011). Other studies (Dresselhaus and Terrones, 2013) showed that N-doped MWCNTs did not show an inflammatory response. Oxidatively degraded SWCNTs did not induce lung inflammation or toxicity following pharyngeal aspiration in mice (Kagan et al., 2010), providing proof-of-principle for deliberate design of engineered CNTs that are biodegradable and less likely to induce acute or chronic disease following inhalation or injection for tumor imaging or drug delivery (Bianco et al., 2011). Graphene oxide nanosheets have also been shown to be degraded in the presence of horseradish peroxidase and H_2O_2 (Kotchey et al., 2011) or by *Shewanella* bacteria that chemically reduce graphene oxide to graphene (Salas et al., 2010). These studies provide novel approaches for biodegradation of ENMs and prevention of long-term adverse environmental and health impacts.

Chemical Transformation The dissolution and degradation processes discussed above are a subset of the larger class of "chemical transformation" that nanomaterials can undergo in the natural environment or in biological tissue. Most nanomaterials are synthesized with the input of chemical or thermal energy and when transferred into environmental or biological fluid phases they seek to release this free energy by chemical transformation into more stable phases. Chemical transformations include dissolution to soluble molecular species, degradation to complex solid debris, or chemical reaction to form new solid phases that include sulfides, selenides, or oxides (Liu et al., 2012; Lowry et al., 2012). Such transformations can dramatically alter nanomaterial properties, and require

that studies of hazard and risk be extended beyond the pristine particles to include the transformation products. Transformations can occur between the points of synthesis and exposure during nanomaterial processing, handling, storage, use, or upon release into the natural environment. These transformations complicate nanotoxicology studies, because nanoparticle properties become a complex function of sample history, which in many cases is unknown and uncontrolled. Transformation can also occur after exposure through contact with biological fluids or tissues causing the potential toxic properties of particles to evolve over time.

One of the most studied nanomaterials in the transformation literature is metallic nanosilver. Nanosilver has been shown to undergo oxidative dissolution in the presence of atmospheric O_2 accompanied by Ag^+ ion release (Liu and Hurt, 2010), and because the silver ion is more toxic than the particles in many biological systems, the location and extent of this ion release is a key factor determining nanosilver toxicity. Further transformations include chemical or photochemical reduction of the silver ions back to nanosilver particles, referred to as "secondary particles" (Glover et al., 2011); reaction with reduced sulfur species to form the stable and highly insoluble silver sulfide (Lowry et al., 2012); and reaction to form solid selenides (Liu et al., 2012). These transformations are thought to play a role in the formation of silver-containing solid deposits in tissue that give rise to argyria, which is a skin discoloration phenomenon that has been observed in humans exposed orally to high doses of nanosilver (Liu et al., 2012).

Insights into the novel findings of bioprocessing and biotransformation of ENMs at subcellular, almost atomic levels are addressed by Graham and colleagues (2014, 2017).

THE NANOMATERIAL BIOLOGICAL INTERFACE

The high surface area of NPs provides a platform for adsorption of a variety of biological molecules including proteins, lipids, and nucleic acids. Dawson and his coworkers described in detail rapid binding of proteins in biological fluids to the surface of NPs that they defined as the "protein corona" (Lynch et al., 2007). The protein corona is a dynamic interface between the NP and its local environment that governs its initial interaction with target cells (Dutta et al., 2007; Walczyk et al., 2010). The interaction of nanomaterials with blood plasma proteins has been investigated in most detail due to its importance in drug delivery, circulation time, organ distribution, and clearance (Karmali and Simberg, 2011). Protein adsorption is related to surface charge, hydrophobicity, and radius of curvature; however, NPs of diverse chemical composition and structure (e.g., iron oxide NPs, polymeric NPs, and CNTs) avidly adsorb albumin, complement, fibrinogen, immunoglobulins, and apolipoproteins (Nel et al., 2009). Protein adsorption and dissociation is a complex, dynamic phenomenon (Cedervall et al., 2007a, 2007b). Quantitative techniques to predict and characterize protein adsorption have been developed (Xia et al., 2010). The consequences of protein adsorption to NPs are less clear; although, depending on the NP surface, proteins may denature, resulting in the loss of normal structure and function, or altered enzyme activity, or unfolding that exposes new antigenic determinants. NPs of diverse chemical composition also induce protein fibrillation or aggregation to form amyloid fibrils in an acellular system (Linse et al., 2007). An important potential pathological consequence of serum protein adsorption to NPs is binding of fibrinogen leading to formation of blood clots (Khandoga et al., 2010).

NPs that are inhaled into the respiratory tract or ingested into the gastrointestinal tract encounter a mucus layer that provides a natural barrier to penetration of particulates and microorganisms. Mucus is a complex glycoprotein composed of hydrophilic, dispersed regions and hydrophobic, globular domains. NPs may adhere to mucins causing enlargement of the pore size with increased susceptibility to penetration of microorganisms (Shvedova et al., 2007; Wang et al., 2011b). Smaller, charged NPs may be repelled by the hydrophilic domains and will not be able to penetrate the mucus layer (Cone, 2009; Lai et al., 2009; Wang et al., 2011b). Aquatic organisms (Klaine et al., 2008) and bacterial biofilms (Rodrigues and Elimelech, 2010) are surrounded by similar extracellular barriers that may prevent NP penetration. If inhaled NPs deposit in the alveoli of the lungs, they encounter the lung lining fluid covering a thin film of surfactant lipids. Natural or synthetic lung lining fluid, which is a mixture of serum albumin and dipalmitoylphosphatidylcholine, binds readily to a range of NPs and enhances their dispersion for use in toxicological assays (Sager et al., 2007; Porter et al., 2008).

Some ENP-types also bind nucleic acids and have been proposed as gene delivery devices (Chou et al., 2011). Depending on their chirality, SWCNTs may show sequence-specific DNA binding (Tu et al., 2009). Graphene oxide nanosheets preferentially bind single-stranded RNA or DNA and protect it from enzymatic degradation (Lu et al., 2010). Small graphene oxide nanosheets can also intercalate into double-stranded DNA and induce DNA breaks in the presence of Cu^{2+} ions (Ren et al., 2010). Size-dependent binding of gold NPs into the major groove of DNA has also been reported (Schmid, 2008).

TOXICITY MECHANISMS

The emerging nanotechnology industry has generated fear and distrust among the public about unpredictable toxicity and unintended consequences of human exposure to ENMs (Bainbridge, 2002; Cobb and Macoubrie, 2004). Despite these concerns, there has not yet been an outbreak of human disease associated with exposure to ENMs, although potentially long latency periods between exposure and manifestation of effects require continued vigilance to prevent future problems. The mechanistic pathways associated with toxicity that have been discovered using various in vitro and in vivo assays may be predictable based on the physicochemical properties of ENMs (Meng et al., 2009; Nel et al., 2009). Some of these toxicity pathways were identified by studying UFPs associated with ambient air pollution (Xia et al., 2006), whereas others are the consequence of intracellular release of toxic metal ions. These are in vitro results, but not validated with relevant exposures (Xia et al., 2008b). Oxidative stress due to direct generation of ROS at the surface of NPs or indirectly by target cells following internalization of NPs (Unfried et al., 2007) is a common mechanism responsible for toxicity of ENMs. The most vulnerable subcellular organelles and physiological functions that can be perturbed by exposure to ENPs are summarized in Table 29-3. Depending on the dose, duration of exposure, type of NP, and the target cell, the cellular responses may be minimal and reversible, involve activation of adaptive responses, or severe, leading to significant changes in cell structure and function that may culminate in cell death (Meng et al., 2009). Specific examples of toxicity endpoints induced by exposure to ENMs will be used to summarize our current understanding of mechanisms relevant for nanotoxicology. Most of the mechanistic studies use a variety of in vitro cellular toxicity assays and relatively high concentrations for 24 to 48 hours of exposure. As discussed in detail below, extrapolation from these short-term, high-concentration exposures in vitro to chronic, low-dose exposures in vivo is problematic. Given the wide range of ENMs currently in commercial

Table 29-3

In Vitro Mechanisms of Nanoparticle Toxicity

1. Damage to cell wall and plasma membrane
2. Interference with electron transport and aerobic respiration
3. Induction of oxidant stress
4. Activation of cell signaling pathways
5. Perturbed ion homeostasis
6. Release of toxic metal ions from internalized nanoparticles
7. Disruption of lysosomal membrane integrity
8. Incomplete uptake or frustrated phagocytosis
9. Interference with cytoskeletal function
10. DNA and chromosomal damage

production or in the early development stages, understanding toxicity pathways is essential for developing a rationale strategy for in vitro screening and prioritization for chronic animal testing based on new principles for toxicity testing in the 21st century (Simmons et al., 2009; Walker and Bucher, 2009; Silbergeld et al., 2011).

The cell wall of bacteria and the plasma membrane of eukaryotic cells are the initial barriers to penetration of NPs into target cells. Both gram-negative and gram-positive bacteria have thick cell walls composed of complex lipids and peptidoglycans, respectively. Bacteria do not actively take up particulates; however, several investigators have shown direct physical penetration of bacterial cell walls especially by SWCNTs (Kang et al., 2007, 2008; Liu et al., 2009), graphene and graphene oxide nanowalls (Akhavan and Ghaderi, 2010), and zinc oxide NPs (Liu et al., 2009). Carbon nanomaterials are proposed to act as "nanodarts" creating holes in the plasma membrane, resulting in extracellular release of cytoplasmic contents as assessed by efflux of ribosomal RNA and decreased survival (Liu et al., 2009).

A wide range of NPs have been designed to facilitate delivery of imaging agents, genes, proteins, and drugs into mammalian cells: metallic and iron oxide NPs, silica NPs, quantum dots, biocompatible polymers, liposomes, micelles, and dendrimers (Chou et al., 2011). Target cells may recognize untargeted NPs that bind to surface scavenger receptors (Kanno et al., 2007; Hirano et al., 2008), lectin receptors (Zhang and Monteiro-Riviere, 2010), and Toll-like receptors that recognize hydrophobic domains (Seong and Matzinger, 2004). NPs can also be designed to target specific cell surface receptors triggering internalization by phagocytosis, macropinocytosis, or endocytosis mediated by clathrin, caveolae, or lipid rafts (Nel et al., 2009; Lajoie and Nabi, 2010). In order to facilitate gene, protein, or drug delivery, NPs can be engineered to escape from endosomes or lysosomes by coating with pH-sensitive polymers, viral capsids, cations, or biodegradable carriers (Chou et al., 2011).

Eukaryotic cells can actively internalize a variety of ENPs using energy-dependent, receptor-mediated endocytosis or phagocytosis (Zhao et al., 2011). Following endocytosis or phagocytosis, NPs follow a well-defined intracellular pathway usually leading to fusion with lysosomes (Oh and Swanson, 1996). The kinetics and mechanisms of cell uptake vary, depending on the target cell, size, shape, and surface modifications (Chithrani, 2010). Most NPs and microparticles are stored in membrane-bound vesicles, endosomes, or phagosomes; however, a subset of NPs including mesoporous silica NPs and superparamagnetic iron oxide NPs coated with chitosan undergo exocytosis or release from endothelial cells (Slowing et al., 2011) and macrophages (Serda et al., 2010). Exosomes are derived from sorting endosomes and multivesicular bodies; smaller NPs show greater exocytosis than particles in the range of 30 to 50 nm (Chithrani, 2010; Serda et al., 2010). Selective coating of NPs to favor delivery to exosomes can be exploited for drug delivery to vascularized tumors or to promote cell–cell transfer of genes and proteins (Slowing et al., 2011).

NPs that are recognized by surface receptors may activate cell-type-specific signaling pathways leading to cell proliferation or death by apoptosis, stress-related signaling, or calcium-mediated signal transduction events (Unfried et al., 2007). Dysregulated intracellular calcium ion homeostasis may be the consequence of influx across a damaged plasma membrane permeability barrier or release of calcium ions from the major intracellular storage sites, mitochondria, and endoplasmic reticulum. Sustained elevation in intracellular calcium can cause cell death by necrosis (Xia et al., 2006).

In addition, small polystyrene NPs and metallic NPs and dendrimers have been shown to enter a variety of target cells by passive diffusion in an energy-independent process (Lesniak et al., 2005; Geiser et al., 2005). Following uptake by diffusion, these small NPs are not compartmentalized into membrane-bound vesicles or lysosomes but are found free in the cytoplasm where they may secondarily enter the mitochondria or even the nucleus.

Mitochondria are the site of aerobic respiration and generation of adenosine triphosphate (ATP). Small NPs have been observed inside mitochondria (Li et al., 2003; Xia et al., 2006) where they may disrupt electron transport in the inner mitochondrial membrane and generate excess endogenous ROS. Direct or indirect generation of ROS in target cells exposed to a variety of engineered or ambient NPs is a major mechanism leading to cell toxicity and cell death (Nel et al., 2006; Unfried et al., 2007). Excess ROS that are not detoxified by endogenous antioxidant defenses can damage cellular membranes via lipid peroxidation, inactivate structural proteins, enzymes, and ion pumps, and damage nuclear DNA. A "hierarchical stress response" to oxidant-induced injury has been proposed by Nel et al. (2006). Low levels of ROS can activate transcription factors leading to upregulated expression of antioxidant defense-related genes. The second tier of response to ROS is activation of redox-sensitive transcription factors that upregulate genes involved in inflammation, pro-inflammatory cytokines, and chemokines (Albrecht et al., 2004). Finally, high or sustained production of ROS can lead to irreversible mitochondrial injury and cell death by apoptosis or necrosis (Nel et al., 2006).

Endocytosis and phagocytosis of NPs by target cells usually results in fusion with and sequestration in membrane-bound lysosomes (Russell et al., 2009; Chithrani, 2010). Uptake of quantum dots, CNTs containing metal catalyst residues, or metallic and metal oxide NPs provides a pathway for intracellular delivery of toxic metal ions by a "Trojan horse mechanism" (Limbach et al., 2005). In the acidic environment of lysosomes, cadmium ions can be released from quantum dots, redox-active iron from iron oxide NPs, and other toxic metal ions including nickel from CNTs or metallic and metal oxide NPs (Liu et al., 2008; Pietruska et al., 2011). This mechanism may also be exploited to release drug cargoes into the cytoplasm following NP-mediated delivery (De Jong and Borm, 2008).

Cellular uptake of long, rigid, high aspect ratio nanomaterials including CNTs, metallic nanowires, and nanorods is especially hazardous for target cells in the lungs (Donaldson et al., 2010). Macrophages are the initial cells to phagocytize inhaled particulates deposited in the airways or alveoli (Geiser and Kreyling, 2010). Rigid, high aspect ratio ENMs show similar interactions with macrophages as amphibole asbestos fibers. If they are longer than the diameter of macrophages (~10 μm), rigid elongated nanostructures show incomplete uptake or phagocytosis with prolonged generation of ROS by the respiratory burst mechanism of phagocytes

and extracellular release of damaging lysosomal enzymes. Rigid, high aspect ratio nanomaterials also cause permeabilization of the lysosomal membrane, resulting in the release of cathepsins into the cytoplasm and activation of the inflammasome (Hamilton et al., 2009). Cathepsins are proteases active at neutral pH and can cleave precursors of pro-inflammatory cytokines that can initiate inflammatory reactions in the lungs (Biswas et al., 2011) as well as activate procaspases leading to death by apoptosis (Boya and Kroemer, 2008). Activation of the inflammasome, the cytoplasmic protein complex where this proteolytic cleavage and activation occurs, is also triggered by uptake of crystalline minerals including silica and asbestos fibers (Dostert et al., 2008).

Incomplete sequestration of long, rigid, high aspect ratio NPs in lysosomes may also promote their release into the cytoplasm, resulting in physical interference with cytoskeletal function. Cytoskeletal disruption can cause impaired cell motility; for example, macrophage-mediated clearance of asbestos fibers and high aspect ratio NPs is impaired, resulting in sustained lung injury, inflammation, and fibrosis (Donaldson et al., 2010) as discussed below. In other organs, NP-mediated interference with cytoskeletal-mediated transport may occur, for example, impaired bile transport and secretion by hepatocytes (Johnston et al., 2010a). In dividing cells, high aspect ratio NPs may physically interfere with the mitotic apparatus, resulting in chromosomal mis-segregation and polyploidy (Sargent et al., 2010).

Finally, NPs may translocate into the nucleus by diffusion through nuclear pores or via nucleocytoplasmic transport (Unfried et al., 2007). Quantum dots (Hoshino et al., 2004), silicon dioxide NPs (Chen and von Mikecz, 2005), and gold NPs (Pante and Kann, 2002) have been detected in the nucleus. Small gold NPs may intercalate into DNA (Schmid, 2008) and generate ROS that may induce oxidative DNA damage (Kang et al., 2010). Silicon dioxide NPs have been shown to induce intranuclear protein aggregates of histones, topoisomerase I, and fibrillarin, although the functional consequences of this intranuclear protein aggregation are unknown (Unfried et al., 2007).

CAVEATS IN NANOTOXICOLOGY ASSAYS

The unique physical and chemical properties of solid materials at the nanoscale contribute to serious technical limitations and potentially misleading results using conventional toxicology assays (Petersen et al., 2014; Rosslein et al., 2015). Due to their high surface area and hydrophobicity, NPs can adsorb vital dyes, cell culture micronutrients, or released cytokines (Monteiro-Riviere and Inman, 2006; Casey et al., 2007, 2008; Guo et al., 2008; Stone et al., 2009). High surface area carbon nanomaterials such as SWCNTs and graphene have the greatest potential to adsorb aromatic amino acids, vitamins, and fluorescent dyes by π–π interactions with their hydrophobic graphenic surfaces (Guo et al., 2008). Adsorption of bacterial lipopolysaccharide or endotoxin (a component of the cell wall of gram-negative bacteria) is a major concern because even low levels of endotoxin can activate macrophages and dendritic cells (Vallhov et al., 2006). Genotoxicity endpoints are especially sensitive to NP-induced artifacts; for example, particle agglomerates interfere with the comet assay, used to detect DNA breaks, and cytochalasin B used in the cytokinesis-arrested micronucleus assay can interfere with NP uptake (Doak et al., 2009; Stone et al., 2009; Magdolenova et al., 2014; Evans et al., 2017). NP agglomerates in physiological saline may also induce greater cytotoxicity than well-dispersed NPs; however, controls must be included to rule out toxicity of the dispersant (Wick et al., 2007). In all toxicological studies, well-characterized positive and negative reference samples should be included over a range of doses and exposure times using standardized methodology (Pal et al., 2015).

ENMs are highly complex and have unique chemical and physical properties relative to bulk materials of the same chemical composition. Complete materials characterization is required for adequate interpretation of toxicological studies (Warheit, 2008; Stone et al., 2009; Azhdarzadeh et al., 2015). Nanotoxicologists must collaborate with chemists, engineers, and materials scientists in an interdisciplinary research team in order to understand the chemical, physical, and structural properties responsible for biological interactions and potential toxicity of nanomaterials. The relevance of in vivo extrapolation from high-dose, short-term, in vitro toxicity assays is discussed in more detail below.

SAFETY CONSIDERATIONS IN NANOMATERIAL DESIGN

In principle, it should be possible to engineer NPs with desirable surface properties for commercial or biomedical applications, for example, to control their size and geometry in order to prevent indiscriminate entry into cells and frustrated phagocytosis. Capping or coating of NPs using antioxidants such as tocopheryl-polyethyleneglycol-succinate (Yan et al., 2007) may decrease toxicity. Release of toxic metal ions from quantum dots and iron oxide NPs can be minimized using inorganic shells or biocompatible polymers such as chitosan or alginate (De Jong and Borm, 2008). CNTs, fullerenes, and graphene are easily surface functionalized; for example, covalent functionalization with carboxyl groups has been reported to decrease toxicity of these pristine carbon nanomaterials (Sayes et al., 2005, 2006; Sasidharan et al., 2011). There is evidence that CNTs are less pathogenic if short in length, or if entangled to hide their fibrous nature (Poland et al., 2008). A long-term goal of mechanistic nanotoxicology is to reveal structure–activity relations that may allow the design of safe nanomaterials through re-engineering or reformulation (Hutchison, 2008).

CASE STUDY: DESIGNING SAFER SUNSCREENS

Zinc oxide and TiO_2 NPs are widely used in sunscreens because they show less scattering of visible light and appear transparent, while effectively absorbing UV light in both the UVB and UVA wavelengths (Wang and Tooley, 2011). Due to its rapid dissolution in water releasing Zn^{2+} ions, zinc oxide NPs are considered as potential environmental toxicants (Kahru and Dubourguier, 2010). Xia et al. (2011) deliberately doped zinc oxide NPs with iron (1% to 10% by weight) that significantly retarded release of Zn^{2+} ions in water and physiological saline solutions. Zn^{2+} ions inhibit hatching of zebrafish embryos. Pristine zinc oxide NPs also inhibited hatching; however, iron-doped NPs were less inhibitory in this assay. Similarly, iron-doped zinc NPs induced significantly less lung injury and inflammation than pristine zinc oxide NPs following intratracheal instillation in rodents. This study provides proof-of-principle for safe design of ENPs to minimize potential environmental toxicity and adverse health effects.

TiO_2 NPs are used commercially in sunscreens, cosmetics, catalysts, and photocatalytic coatings for buildings and windows. Nanosized TiO_2 is found in small concentrations (typically $<30\%$ number and less than 1% mass) in food stuffs and personal care products (Weir et al., 2012; Warheit et al., 2015). In 2010, 5000 metric tons of TiO_2 NPs were produced (Landsiedel et al., 2010) and have been detected in effluents from waste water treatment plants where they may enter surface water (Westerhoff et al., 2011).

The potential of zinc oxide and TiO_2 NPs to induce phototoxicity and penetrate into the dermis has been a concern for human safety of sunscreens (Wang and Tooley, 2011). These mineral-based sunscreens cause less skin irritation and produce fewer allergic reactions than chemical-based sunscreens. The pristine NPs used in sunscreens form aggregates 30 to 150 nm in diameter; in this size range, these NPs are photoreactive and may generate ROS. Although uncoated TiO_2 NPs exhibit phototoxicity, following coating with hydrophobic stabilizers used in sunscreen formulations, no phototoxicity was detected in a cell culture assay system (Schilling et al., 2010). A series of skin penetration studies using both ex vivo and in vivo models also showed that these NPs do not penetrate deeper than the outer most layer or stratum corneum of intact skin (Schilling et al., 2010). However, TiO_2 NPs suspended in cyclopentasiloxane fluid used in cosmetics did penetrate into hair follicles of shaved skin of micropigs (Senzui et al., 2010). Finally, young pigs were exposed to UVB light producing sunburn and an in vitro skin perfusion system was used to assess penetration of sunscreens containing zinc oxide or TiO_2 NPs. Only superficial penetration into the upper layers of the epidermis was observed and no zinc or titanium above untreated control levels was observed in the perfusate (Monteiro-Riviere et al., 2011). Finally, 36 weekly applications of sunscreens containing TiO_2 or zinc oxide nanoparticles plus ultraviolet radiation applied to hairless mice did not induce any adverse systemic effects or skin tumors in comparison to mice exposed only to ultraviolet radiation (Osmond-McLeod et al., 2016). Collectively, these in vitro and in vivo toxicology assays suggest that the benefits of protection against carcinogenic UV light radiation provided by sunscreens formulated with zinc oxide or TiO_2 NPs outweigh the minimal risks associated with phototoxicity, DNA damage, and skin penetration into shaved or sunburned skin.

MAMMALIAN TOXICOLOGY

Introduction

Nanotoxicology, the science of effects of ENMs on living organisms, is a rapidly growing discipline aimed at identifying and characterizing nanomaterial toxicity that will serve—in combination with exposure data—the ultimate goal of performing a meaningful risk assessment (National Academy of Sciences, 1983). Many ENMs exhibit unique and desirable catalytic, optical, structural, or electronic properties that make them attractive in diverse technological areas, including multiple manufacturing industries and environmental and medical applications. At the same time, concerns have been raised regarding potential acute and chronic adverse effects due to their physicochemical properties in combination with nanostructures, for example, an elongated fiber-like shape of CNTs (Johnston et al., 2010b).

CNTs are a prime example of the two opposing faces of nanomaterials: Many highly desirable properties that are suitable for numerous beneficial applications contrast with reports of serious adverse effects in experimental animals. For example, the excitement about future uses of CNTs in biomedical applications for delivery of drugs, genes, and biosensors or as tissue engineering scaffolds (Liu et al., 2008, 2010b; Liang and Chen, 2010) is dampened by reports of inflammatory fibrogenic and even mesotheliogenic effects in laboratory rodents (Shvedova et al., 2005; Takagi et al., 2008; Jacobsen et al., 2008; Poland et al., 2008; Sakamoto et al., 2009). Results of a number of in vitro studies in different cell systems also revealed an oxidative stress-inducing pro-inflammatory potential of CNTs (Monteiro-Riviere et al., 2005; Pacurari et al., 2008; Hirano et al., 2010; Vankoningsloo et al., 2010; Sanchez et al., 2011); however, other in vitro studies did not confirm such effects (Fenoglio et al., 2006; Flahaut et al., 2006; De Nicola et al., 2007; Pulskamp et al., 2007).

As discussed earlier, a common problem with in vitro studies is that very high doses/concentrations in culture media are used that have no relevance for realistic in vivo conditions. Moreover, results of in vitro assays can be misleading due to interference of the nanomaterials to be tested with the testing reagents, adsorption of induced mediators (Worle-Knirsch et al., 2006; Han et al., 2011), or interference with optical measurements (Pfaller et al., 2010); general problems related to sensitivity and reliability of in vitro systems have also been discussed (Jones and Grainger, 2009). A most recent example of reliability problems of in vitro assays in evaluating the toxicity of CNTs is described by Haniu et al. (2011) who reported contradictory results of increased as well as decreased cell viability as well as either no or high cytokine release when the same CNT and the same cell type were dosed using different dispersants for pretreatment.

Concepts of Nanotoxicology

The previous section discussed the importance of physicochemical properties of ENM. Fig. 29-8 summarizes several of these properties that are known to affect biological/toxicological effects. The size and size distribution are important determinants—aerodynamic—for the deposition efficiency of inhaled materials throughout the respiratory tract (see Fig. 29-8). The quality of dispersion in liquid media can be determined by measuring the hydrodynamic diameter, which is important information for in vitro studies and the ENM behavior in blood and lymph circulation. The shape of ENM (tubes, fibers, planes) influences their aerodynamic and hydrodynamic behavior and is of special significance for cellular uptake, for example, a fiber shape of straight nanotubes with a length exceeding the diameter of alveolar macrophages so that they cannot be completely phagocytosed (frustrated or incomplete phagocytosis) resulting in potent activation and release of inflammatory mediators (Kane and Hurt, 2008). Individual NPs tend to agglomerate (held together by relatively weak forces, e.g., Van der Waals forces) or they are aggregated when produced (sintered together or firmly bundled in the case of fibers) (ISO/TS 27687, 2008; Teleki et al., 2008; Taurozzi et al., 2011). Oftentimes, larger structures in the form of agglomerated aggregates are formed (Fig. 29-8), both in the airborne state and as liquid suspensions.

The terms "agglomeration" and "aggregation" are often used interchangeably, yet ISO/DIS (2011) defines them as based on the forces that keep the primary particles together (agglomerates: weakly bound with external surface area similar to the sum of surface areas of individual components; aggregates: strongly bonded or fused with the external surface significantly smaller than the sum of calculated surface areas of individual components). Both agglomerates and aggregates are also termed "secondary particles" (ISO/DIS, 2011).

The formation of agglomerates of aerosols (coagulation) depends on their number concentration in the airborne state and is a function of time (Hinds, 1982). The effect of such time-dependent agglomeration on decreasing the number of airborne particle concentration and on increasing the overall particle size is illustrated in Table 29-4 assuming simple monodisperse coagulation in still, undisturbed air. For example, it takes only 20 minutes for a very high number concentration of 10^{14} particles/cm^3 to decrease by half, whereas it takes 231 days if the initial concentration is only 100 particles/cm^3. Similarly, in order to double the initial particle size because of a resulting increase in the agglomerate particle size,

Table 29-4

Time for Number Concentration to Halve and Particle Size to Double by Simple Monodisperse Coagulation

STARTING AIRBORNE CONCENTRATION (number/cm³)	TIME TO REACH HALF THE CONC. (½ N_s)	TIME TO DOUBLE PARTICLE SIZE ($N_D = 0.125\ N_s$)
10^{14}	20 μs	140 μs
10^{12}	2 ms	14 ms
10^{10}	0.2 s	1.4 s
10^{8}	20 s	140 s
10^{6}	33 min	4 h
10^{4}	55 h	16 days
10^{2}	231 days	4 year

SOURCE: Data from Hinds (1982).

it takes 140 μm for the initially very high concentration, but 4 years for the low concentration. This dramatic shift in particle size distribution needs to be considered when high concentrations of airborne NPs are measured close to their source.

The agglomeration and the aggregation state of ENM will significantly influence their bulk and apparent density. For example, the specific density of TiO_2 is ~4 g/cm³, whereas the bulk density (density of a powdered material including interparticle spaces) of nano-TiO_2 depending on primary particle size ranges from 0.13 to 0.54 g/cm³. Bulk density—interchangeably also described as apparent or packing density—can be measured by pouring the ENM powder into a fixed volume of a graduated cylinder (freely settled). The volume of the measured mass/cm³ includes the particle volume, the interparticle void volume, and any internal pore volume. Using multiwalled carbon nanotubes (MWCNTs) as an example, the specific density of the base material, carbon, is ~2 g/cm³, but the bulk density of MWCNT was reported as ranging between 0.043 and 0.31 g/cm³ (Ma-Hock et al., 2009; Pauluhn, 2010). The density achieved by packing of individual agglomerate structures of different MWCNTs obviously plays an important role for differences of the bulk or packing density, as do the dimensions of length and diameter, the straightness of the tubes, and the form and size of tangled structures. Knowledge of bulk density is important for understanding the aerodynamic behavior of ENM and their deposition in the respiratory tract. In simple general terms, the aerodynamic diameter (D_{ae}) of an aerosol is correlated with the physical geometric particle diameter (D_{geom}) as $D_{ae} = D_{geom} \times \sqrt{\rho}$ (ρ = material density in g/cm³). For particles below 1 μm, a slip-correction factor needs to be added. For highly agglomerated ENM, it is preferable to replace the true material density with the value of bulk or apparent density in order to more accurately estimate the aerodynamic diameter.

A low bulk density obviously increases the volume of ENM after uptake into cells relative to the volume occupied by the same mass of non-agglomerated material. A volumetric overload concept for alveolar macrophages has been proposed by Morrow (1988), who suggested that when a phagocytized volume of 60% of the normal macrophage volume is reached, movement and clearance function of macrophages is completely abolished, and that a retardation of the clearance function of macrophages starts when ~6% of the cell's volume is exceeded by phagocytized particles. Pauluhn (2010) applied this concept of volumetric overload to results of his subchronic inhalation study with MWCNT in rats for estimating an occupational exposure level (OEL). However, a recent review of this concept by Borm et al. (2015) concluded that a volumetric overload of macrophages does not apply to ultrafine poorly soluble particles. Instead, the particle surface area correlates best with the induced alveolar inflammation and retarded macrophage clearance function.

Surface characteristics of ENM are a critical determinant for interpreting dose–response relationships (surface area as dosemetric), and for nanomaterial cell interactions. Uptake into cells is influenced by their surface charge, surface reactivity, the chemistry of surface coatings (functional groups, polymeric coatings), and also surface defects to the material as-synthesized, or introduced during surface functionalization or processing such as acid purification or ultrasonication for dispersion.

Solubility and solubilization rate are of interest because the shortened biopersistence of NP in the organism terminates any NP-size-related effects. Zinc oxide is an example of an NP that undergoes rapid dissolution, thereby giving rise to high ionic zinc concentrations and induction of inflammation and oxidative stress (Xia et al., 2008b) in contrast to poorly soluble CeO_2 or TiO_2 NPs. Many ENPs are insoluble in the as-produced form (e.g., metallic Ag^+ and Ni^{2+} metallic NPs), and do not undergo simple dissolution, but can undergo chemical oxidation, a kind of nano-corrosion, in solution, in tissue, or in the environment to produce soluble species (e.g., Ag^+ and Ni^{2+}) in a process that gradually degrades and eliminates the particle state (Liu and Hurt, 2010; Liu et al., 2010a; Pietruska et al., 2011). Such NPs can act via a "Trojan Horse" mechanism in that they are taken up into cells and subsequently dissolve, thereby creating a very high intracellular ionic metal concentration that is cytotoxic (Limbach et al., 2007). The same ionic concentration outside the cell will elicit no or only a modest response because of selective cell barriers preventing metal ions from entering the cell. The results by Xia et al. (2008b) and Limbach et al. (2007) are based on in vitro studies. Donaldson et al. (2009) have cautioned that great care should be taken in interpreting that oxidative stress induction by particles observed in vitro will also occur in vivo. This is not to say that the "Trojan Horse" effect does not occur in vivo; it has been described and is being used in designing drug delivery via NP for therapeutic applications (Kreuter, 2004; Iezzi et al., 2012). The cautionary note is more generally directed toward the extrapolation of in vitro-based oxidative stress results to in vivo conditions.

It is a major challenge for nanotoxicological studies that many of these properties, once they have been determined for a given ENM, are not stable but can change when prepared for toxicological testing or during storage or testing. The fact that alterations can occur through oxidation or dissolution (above), or through adsorption of proteins and lipids once they have been taken up into different compartments of the organism, has become an important area of research (Cedervall et al., 2007a, 2007b; Lundqvist et al., 2008; Monopoli et al., 2011), yet methods to study these changes on the surface of ENMs in vivo still need to be developed.

Dosemetrics

Given the importance of physicochemical properties of ENM as determinants of their biological/toxicological properties, the question of the proper dosemetrics has been raised. Toxicologists are used to thinking in units of mass or molarity when characterizing a dose or concentration. However, several in vitro and in vivo studies with NP have shown that expressing dose–response relationships on a convenient mass basis may not be as informative as the surface area of the NP (Oberdörster et al., 1992; Donaldson et al., 1996;

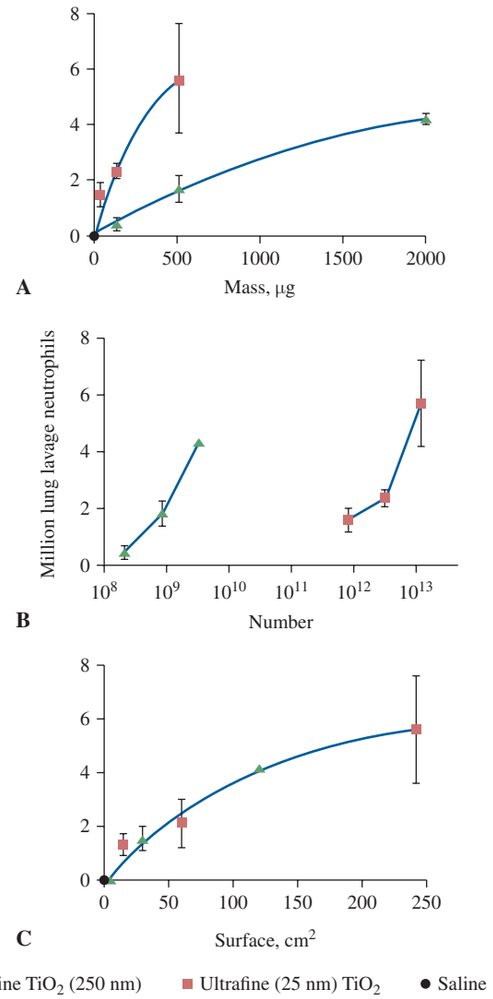

Figure 29-10. *Inflammatory cell response (neutrophil number in lung lavage of rats 24 hours after intratracheal instillation of two sizes of TiO_2 particles expressed by different dosemetrics.* Particle-mass (**A**); -number (**B**); -surface area (**C**). (Reproduced with permission from Oberdörster et al. [2007a].)

Tran et al., 2000). Fig. 29-10 shows the pulmonary inflammatory dose–response relationships of two sizes of TiO_2 particles induced by intratracheal instillation in rats. A significantly greater influx of inflammatory neutrophils into the lung was induced by 25 nm TiO_2 per unit mass than by 250 nm TiO_2. The result is a very steep dose–response for the nanosized TiO_2 and a flatter dose–response for the larger TiO_2. Likewise, there was a clear separation of the dose–response when based on the number as dosemetric; however, when the same data were expressed based on particle surface area, a common dose–response relationship emerged (Fig. 29-10).

Although the concept of particle surface area as dosemetric is biologically plausible because it is the surface of particles that interacts with cell structures, the total surface area may only be a surrogate of the actual biologically relevant surface. As was discussed above, there are a number of surface properties (Fig. 29-8) that affect interaction with cells. Thus, identifying a biologically available surface area will be of great value for defining a proper dosemetric. At present, the specific surface area of ENMs (m^2/g) is most commonly measured by vapor adsorption, in which the number of vapor molecules (usually nitrogen) adsorbed on solid surfaces is quantified over a range of standard conditions and the surface area estimated by application of the BET theory (Brunauer et al., 1938). Both the external and existing inner surface (porosity) in pores larger than the nitrogen molecule are determined by this technique. There is a need for standardization of the method with regard to the use of nitrogen or other gases (Kr; Ar) because different molecule sizes will "see" and report different surface areas in molecular-sized pores (<0.4 nm). Measurements of BET surface area can also contribute to differentiation between agglomerated and aggregated structures; for example, agglomerated NPs have essentially the same specific surface area as the same mass of individual primary particles, whereas aggregated particles have a somewhat lower specific surface area than the same mass of primary particles (ISO/TS 27687, 2008). The measured surface area can then be converted to a BET equivalent particle size for nonporous spherical particles (Teleki et al., 2008).

In addition to mass, number, and surface area as dimensions for a dosemetric, the volume of NPs has been suggested as another dosemetric. This suggestion is based on the interpretation of earlier long-term inhalation studies in rats in which very high concentrations of different poorly soluble particles of low cytotoxicity had resulted in highly overloaded alveolar macrophages so that their normal clearance function was severely impaired or had come to a standstill. Based on the results of these studies, Morrow (1988) formulated a "particle overload" hypothesis: When the volume of phagocytized particles in alveolar macrophages exceeds 6% of the normal macrophage volume, their physiological clearance function becomes impaired; if the phagocytized volume reaches 60%, the clearance function ceases completely. For certain ENMs the volume that they occupy can be very high, for example, larger agglomerates of MWCNT, forming a loosely packed (low specific density) structure that takes up a large volume when taken up by alveolar macrophages in the lung. Pauluhn (2010) has applied this volumetric overload concept to results of a well-performed subchronic rat inhalation study for estimation of a human occupational exposure limit.

Follow-up studies to the mechanistic basis of lung particle overload points to particle surface area of agglomerated phagocytized nano and larger particles as dosemetric, which appears to correlate better with the impaired clearance function of alveolar macrophages rather than the phagocytized volume (Oberdörster et al., 1994; Tran et al., 2000). Borm et al. (2015) pointed out in a recent update that a volumetric overloading of alveolar macrophages following repeated inhalation by rats of high concentrations of poorly soluble ultrafine particles (TiO_2) does not correlate with the induced alveolar inflammation or the impaired alveolar macrophage clearance function. Rather, the surface area of the retained phagocytized particles should be considered the appropriate dosemetric for UFP. Thus, deriving OELs for ENMs from results of chronic rodent inhalation studies based on the volumetric lung particle overload concept is scientifically not justified. Yet—as pointed out before—it is important to remember that not only physical—volume, surface area—but also chemical—surface associated—properties of NPs are critical determinants of effects resulting from NP–cell interactions (Fig. 29-8).

Among the different dosemetrics discussed in this section, particle number is of particular importance with respect to characterizing exposure. Exposure concentrations in the air are expected to be very low, which makes it difficult to determine the precise concentration based on measuring mass. However, a low mass of NP consists of a huge number of particles that can reliably be measured in the airborne state using scanning mobility particle sizers or concentration particle counters. Thus, NP number as an exposure-metric

Table 29-5

Mass/Number/Surface Area Correlations for Selected NPs

for mainly isometric-type NP is a valuable component for exposure characterization.

Table 29-5 shows the correlation among the different dosemetrics of different 50-nm-sized isometric NPs, with specific material densities ranging from 21 to 1 g/cm^3. Volume is not listed in this table because it depends on the bulk or packing density, which is different from the material density because of additional void spaces between the packed NP. Surface area and number per unit mass and per 100 $\mu g/m^3$ air volume vary greatly. The table also shows that a 200-fold change of particle size from 5 nm to 1000 nm results in a more than six orders of magnitude change in number concentration with only a 20-fold change in surface area for all NP (shown for polystyrene in Table 29-5). However, although these correlations can readily be established for dry powders, even when they consist of polydispersed particle sizes, these correlations will change upon inhalation and disposition in the body because of different deposition and biodistribution efficiencies in the lungs and other organs.

Portals of Entry

The respiratory tract, the gastrointestinal (GI) tract, and skin are the main organs of direct exposure to ENM. For medical application, injection (intravenous, intramuscular, subcutaneous, and other) will also be an important entry route into the organism. Intake via the respiratory tract is the most prevalent exposure route for occupational exposures; additives of ENM to food (TiO_2; SiO_2) and potential contamination of food from nanoenabled packaging materials result in exposure via GI tract (Jani et al., 1990, 1994; Hoet et al., 2004; FAO/WHO, 2009; Loeschner et al., 2011). Based on available data, translocation of nanomaterials in vivo across GI-tract epithelial cells seems to be limited. Trouiller et al. (2009), however, described DNA damage in bone marrow cells following very high gavage dosing of rats. Skin exposure via cosmetics and skin-care products occurs, although penetration of healthy skin by NP has not been demonstrated (Schneider et al., 2009; Monteiro-Riviere et al., 2011; Prow et al., 2011). Some penetration of quantum dots (~30 nm) applied to the skin of mice after UV radiation-induced sunburn was found (Mortensen et al., 2008). Because the respiratory tract is a major route for humans to exposure of nanomaterials, the following sections will focus on this portal of entry to discuss biokinetics, effects, and concepts for in vivo and in vitro toxicity testing.

Dosing of the Respiratory Tract

The following sections focus on the respiratory tract as portal-of-entry of airborne ENM.

Dosing of the respiratory tract of laboratory rodents as the portal-of-entry for airborne ENMs is mostly and conveniently done by intratracheal instillation (rats) or oropharyngeal aspiration and intranasal instillation (mice), which administer materials as a bolus in a second or less. However, inhalation is the only physiological method and should be considered the gold standard for exposure to airborne materials. Obvious major differences between bolus-type and inhalation exposures relate to the dose rate (see discussion later), use of anesthesia, the distribution of administered material within the respiratory tract, and the need for special expertise and equipment required for inhalation but not bolus-type exposures. Although most of the differences between inhalation- and instillation-type delivery are well known and have been discussed in a Society of Toxicology (SOT)-sponsored White Paper (Driscoll et al., 2000), the limitations of using and interpreting results from bolus-type dosing are most often not considered (Table 29-6). This white paper concluded with several recommendations when intratracheal instillation can be applied. These included evaluation of comparative toxicity involving screening, ranking, range finding of doses, comparison to reference material; also, evaluation of material not respirable by rodents. In order to minimize interference of clumping and localized inflammation, only <~100 μg/rat should be used. The authors also mention situations when instillation should

Table 29-6

Instillation versus Inhalation

ADVANTAGES	DISADVANTAGES
• Low cost	• Non-physiological
• Simple technique	• Invasive delivery
• Less material needed	• Very high dose rate
• Delivered dose is known	• Usually also high dose, overwhelming lung defenses
• Ranking of toxicities	• Bypassing upper respiratory tract
• Avoiding fur contamination (*handling hazard*)	• Different distribution in lower resp. tract: more central, more heterogeneous, less uniform
• Lower risk to investigators	• Focal high lung burdens
• Nonrodent-respirable aerosol can be delivered (*human health relevant*)	• Potential impact of vehicle on distribution, effects, material to be tested
• Specific areas of lung can be dozed (*larger animals*)	• Potential confounder of anesthesia
• Screening for deciding concentr. for inhalation	• Multiple instillations to reduce heterogeneity
• Identifying toxic components of mixture	

Note: Qualitatively, both methods yield similar results for variety of biologic endpoints (pulmonary inflammation; fibrosis; susceptibility to infection, allergic sensitization, PSP lung tumors), but requires thorough understanding of differences between both methods to avoid misinterpretation of instillation results.

SOURCE: Data from Driscoll et al. (2000).

not be considered: for determining deposition pattern in lung to mimic inhalation; toxic effects in the upper respiratory tract; not to use for materials that react with vehicle; they also cautioned that short-term clearance (mucociliary) is not reflected accurately.

Of special importance is the tremendous difference in the delivered dose rate: Bolus-type delivery occurs within a fraction of a second, whereas inhalation at realistic concentrations takes hours to months of exposure in order to deposit the same dose in the lung. Treating a dose delivered by bolus to be the same as a dose that has accumulated in the lung over a life-long exposure is scientifically not justifiable and needs to be discouraged (Oberdörster, 2012). Inundating cells abruptly with an extraordinarily high dose does overwhelm the cell's defense mechanisms and leaves no time for developing adaptive responses. Consequently, underlying mechanisms of effects induced by such unrealistic high doses are different from those induced by relevant doses and dose rates (Slikker et al., 2004, see Fig. 29-3). With respect to the administered dose rate, Fig. 29-11 (Baisch et al., 2014) illustrates a tremendous difference of inducing a pulmonary inflammation by either intratracheally instilling (~0.5 second duration) 200 µg of TiO_2 NP versus depositing the same dose by inhalation over a period of 4 hours or 4 days (4 × 4 hours). The difference in dose rate is four to five orders of magnitude, with a strong inflammatory response at the highest dose rate (instillation) and no response at the lowest dose rate (inhalation).

Evidence that extremely high doses acutely administered within a very short time overwhelm the organism's or the cell's defenses so an adaptive response cannot be mounted was presented in a rat inhalation study with nanosized particles using exposure to UFPs (~18 nm count median diameter) of polytetrafluoroethylene (PTFE) fumes (Johnston et al., 2000). PTFE fumes, similar to metal fumes, when freshly generated consist of nanosized particles, which are highly reactive and are known to give rise to polymer fume and metal fume fever in occupationally exposed workers (Drinker et al., 1927a, 1927b; Drinker and Drinker,1928; Lee and Seidel, 1991; Seidel et al., 1991). When groups of rats were exposed for 5 minutes on each of 3 days to either filtered air or to a concentration (~50 µm³) of these PTFE fumes, followed on day 4 by a 15-minute exposure of both groups to the same concentration of PTFE fumes, the pre-exposed rats survived without any significant

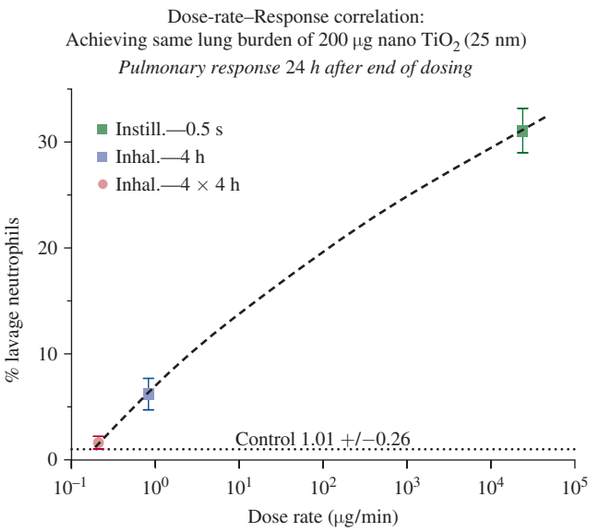

Figure 29-11. *Dose-rate–response correlation.* Deposition of 200 µg nano-TiO_2 in the lungs of rats either by instillation (high dose rate) or by inhalation (low dose rate) induces widely differing pulmonary inflammatory responses as determined by the appearance of inflammatory neutrophils in lung lavage. (Figure provided by G. Oberdörster based on Baisch et al, 2014.)

adverse pulmonary responses (not significantly different from rats that were sham exposed on all days), whereas the filtered air pre-exposed rats died within 3 hours after the 15-minute PTFE exposure (Fig. 29-12A). Estimated deposited dose of PTFE in the lung was only ~60 ng. Further lung tissue analyses revealed that the PTFE pre-exposed rats had mounted a strong "adaptive" response (increased antioxidant and chemokine mRNA), whereas nonadapted rats were unable to induce such a response (Fig. 29-12B). Evidence for such adaptation following inhalation exposure to nanosized particles in humans was already reported eight decades ago when Drinker et al. (1927b) described that repeat exposure to zinc oxide fumes induced "resistance" in human subjects. Adaptive responses are important physiological protective mechanisms, which need to be considered

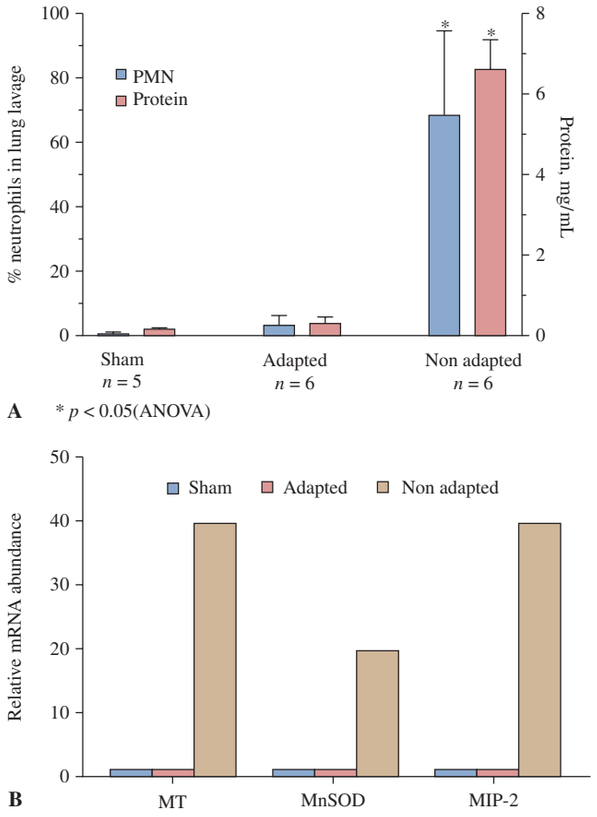

Figure 29-12. *Preventing acute pulmonary injury in rats from inhalation of polymer fume (PTFE, nanosized particles, ~18 nm count median diameter by inducing adaptation with repeated 5-minute PTFE pre-exposures on each of 3 days prior to 15 minutes to exposure on day 4).* (**A**) Adapted rats show no inflammatory response assessed by neutrophil cells in lung lavage; nonadapted rats develop severe lung injury after 15-minute PTFE exposure. Control rats were sham-exposed on all 4 days. (**B**) Change in relative abundance of lung mRNA in PTFE adapted and nonadapted and sham-exposed control rats (Johnston et al., 2000).

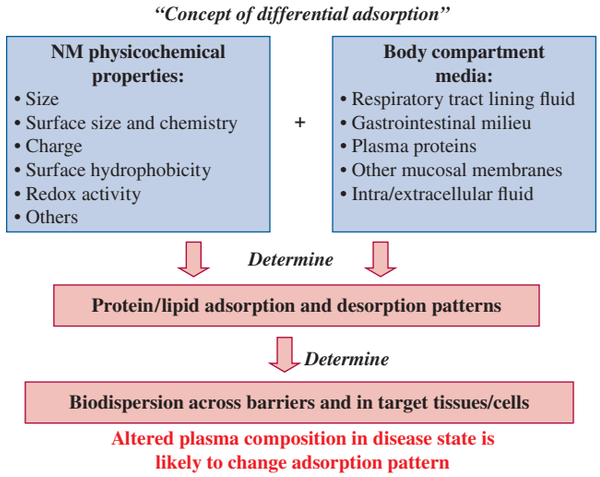

Figure 29-13. *Physicochemical properties of nanomaterials influence the adsorption of proteins and lipids from different organs, which affect the biodistribution of nanomaterials.* (Used with permission from Müller RH, Keck CM. Drug delivery to the brain realization by novel drug carriers. *J Nanosci Nanotechnol.* 2004;May:4(5):471–83.)

when interpreting results of nanomaterial toxicity testing. However, the organism's capacity to adapt may not only be compromised by sudden very high acute exposures of short duration (high dose and high dose rate) but may also be impaired in susceptible parts of the population.

Despite the limitations of bolus-type delivery, they may be viewed as "proof-of-principle" or "hypothesis-forming studies," with the findings to be confirmed by subsequent inhalation studies. Although results from bolus-type studies are useful for toxicity ranking against known positive or negative control ENMs, they cannot be used for quantitative risk assessment. Other in vivo bolus-type deliveries involve intravenous, intraperitoneal, or intrapleural injections. If used for safety assessment of medicinal applications of ENMs, including CNTs, an appropriate range of doses should be applied. However, if intravenous or intracavitary injections are used to simulate doses resulting from translocation of inhaled CNTs after deposition in the lung, results have to be viewed with caution. The amount of NPs translocating from the lung to the blood circulation and subsequently to secondary organs is very low, on the order of 1% to 3% (Kreyling et al., 2002, 2009). Furthermore, the translocation rate from the lung is very low; it occurs over hours and days, which contrasts with the immediate very high dose rate of injection. Bolus-associated problems have been discussed above, and confirmation of results from such "proof-of-principle" studies by follow-up inhalation studies should be mandatory.

The pretreatment of ENMs in preparation of bolus-delivery dosing is an additional difference compared to inhalation and may raise some concern: The recommendation to use dispersants in order to administer the materials in a well-dispersed mode (Fubini et al., 2010; Taurozzi et al., 2011) results in the coating of the treated nanomaterials that changes their surface properties and renders them different relative to their pristine state when inhaled under real-world exposure conditions. Although inhaled ENMs will also be coated by lipids and proteins of the lung lining fluid once deposited, such protein corona is likely to change upon translocation to interstitial and blood compartments based on the "concept of differential adsorption" (Müller and Heinemann, 1989). This concept states that the physicochemical properties of nanomaterials, such as size, surface properties, shape, dissolution, and others when in contact with media in the different body compartments determine protein and lipid adsorption and desorption patterns and thereby influence biodistribution across barriers and in target tissues and cells (Fig. 29-13). This concept has been further developed more recently by Dawson's group (Cedervall et al., 2007a; Lundqvist et al., 2008; Walczyk et al., 2010) who describe the formation of hard and soft protein coronas around NPs upon incubation with blood plasma. Future studies have to show how pretreatment of ENMs for bolus-type in vivo administration will affect both biodistribution and effects. In vitro experiments with various cell types have already demonstrated that the use of different dispersants with MWCNTs resulted in contradictory results (Haniu et al., 2011).

The three different methods of bolus-type dosing of the respiratory tract—intranasal instillation; intratracheal instillation; oropharyngeal aspiration—represent a convenient way to obtain first or preliminary data about effects in the respiratory tract. The limitations and caveats of using these modes of administration—as pointed out in the preceding paragraphs—should be taken into account when interpreting the results. Immediate short-term inflammatory responses will be induced, and these early bolus-associated effects are likely to also influence long-term effects. For example,

when Li et al. (2007) compared pulmonary responses to inhaled and intratracheally instilled MWCNTs in rats, they observed a much lower response in terms of pulmonary pathology after inhalation despite a higher lung burden from inhalation compared to instillation. It is of interest, though, that in another study similar inflammatory, granulomatous, and fibrotic responses were observed in mice following inhalation and oropharyngeal aspiration of SWCNTs. In fact, inhalation exposure was more potent than aspiration of an equivalent mass (estimated) of SWCNTs 1 to 28 days after inhalation exposure to a high concentration (5 mg/m^3, 4 days @ 5 h/day) or oropharyngeal aspiration of 5 and 10 μg (Shvedova et al., 2008). The authors suggested that the similarity of responses between inhalation and aspiration exposure to SWCNTs in mice may be due to smaller SWCNT structures by inhalation of a dry aerosol versus aspiration of a suspension containing micrometer-sized agglomerates. However, both the Li et al. (2007) and Shvedova et al. (2008) studies only estimated the doses deposited in the lung upon inhalation based on inhaled concentration and size distribution and retained doses were not confirmed by actual measurements. In addition, the inhalation exposure by Li et al. was carried out with a static system; that is, MWCNTs were introduced into the exposure chamber as an aerosol and kept there for 90 minutes to slowly settle down while the rats were exposed. This makes it very difficult to determine the actual exposure concentration because it continually decreased, and changes in particle size due to rapid settling of the aerodynamically larger particles will occur. A dynamic exposure system with continuously generated aerosol is the standard and preferred method for inhalation exposures.

Respiratory Tract Deposition

Inhalation by humans of airborne ENM at the workplace or when handling powders of ENM results in significant deposition in the three compartments of the respiratory tract: the nasopharyngeal region from nose/mouth to the larynx; the tracheobronchial region from larynx to terminal bronchioles; and the alveolar region from the first generation of respiratory bronchioles (bronchioles with some alveoli) to the last generation of alveolar ducts. The deposition efficiency of inhaled particles depends on several particle characteristics, the anatomical structure of the airways, and breathing parameters. Particle size, size distribution, density, and shape are most important for their aerodynamic and thermodynamic diameter, which govern deposition in the respiratory tract by inertial impact, gravitational settling, and displacement by diffusion. In addition, interception (in particular for elongated structures or fibers) and electrostatic image forces (positive charge on particles attracted by negative epithelial surface) play a role in certain conditions (see Chap. 15).

Because in vivo toxicological studies are mostly performed in experimental animals, and because of anatomical and some physiological differences in the respiratory system, knowledge about variations in the behavior of inhaled particles is essential for interpreting results of animal inhalation studies with respect to dosimetric *extrapolation* to humans. Several particle deposition models have been developed based on mathematical modeling and supported by results of numerous human studies using inhalation of benign particles of different sizes. The two most frequently used models are the extensive international commission on radiation protection (ICRP) (1994) model for humans, and a user-friendly (computer) Multiple Path Particle Dosimetry (MPPD) model for rats and humans (Asgharian et al., 1999) (available at: MPPD, 2018). Each of these models is based on results of an extensive database of particle deposition studies in humans (ICR Panel MPPD) and in rats (MPPD).

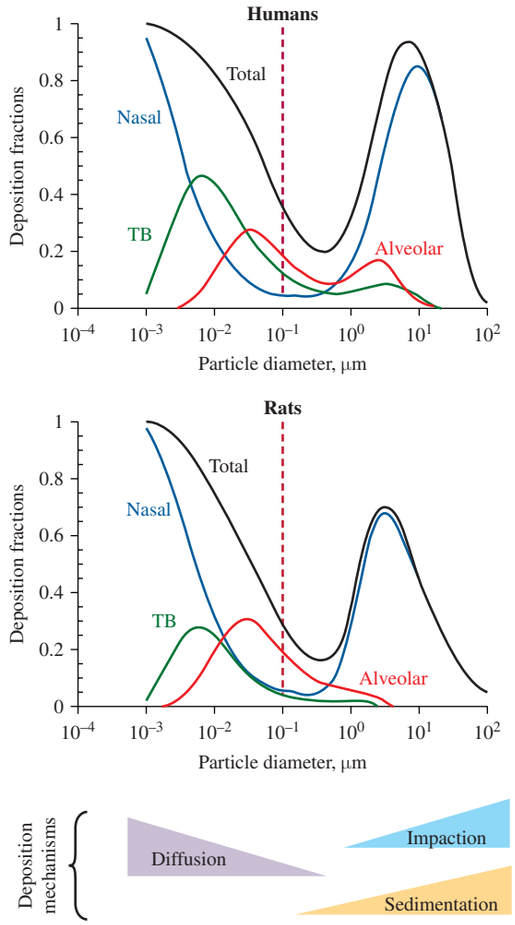

Figure 29-14. *Model predictions of deposition fractions for different particle sizes in humans and rats.* Nanosized particles are left of dashed line (<100 nm); their deposition is governed by diffusion (Brownian motion of air molecules). (Figure provided by B. Asgharian.)

These data have been incorporated into mathematical equations describing airborne particle behavior due to impaction, sedimentation, and diffusion for different airway geometrics in humans and rats. There is good general agreement between results of the two models, although some quantitative differences exist. It should be kept in mind that these are still models to estimate the deposition in the respiratory tract, depending on particle parameters, airway geometrics, and breathing modes. Interindividual time values can be very different from the averages that are calculated by the models.

Fig. 29-14 compares the deposition fractions for monodispersed particles of sizes from about 1 nm to 20 μm diameter between humans and rats based on the MPPD model, assuming unit density material. For both species nasal breathing is assumed, which is the obligatory mode for rats. For NPs below 100 nm (in the thermodynamic size range, less than ~0.5 μm), there is only a small difference in deposition between nasal- and oral-breathing mode, whereas these differences become more pronounced for larger particles in the aerodynamic size range (starting at ~0.5 μm). The mechanisms by which inhaled particles are depositing changes from diffusion (due to bombardment of particles by air molecules) as exclusive mechanism for airborne single NPs to gravitational sedimentation and inertial impaction for the larger particles. Comparing deposition efficiencies between rats and humans, not

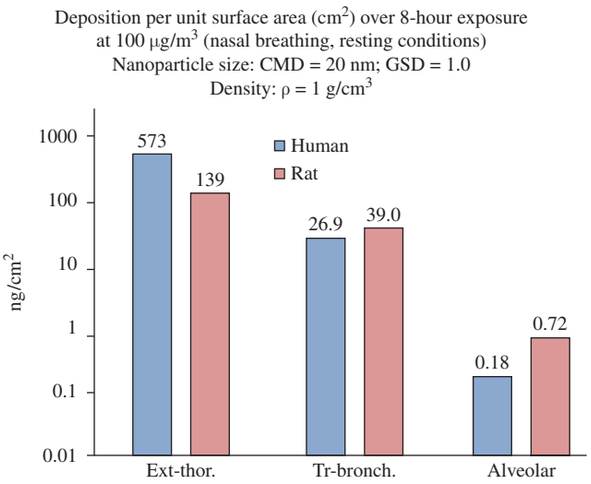

Figure 29-15. *Deposited amount of inhaled nanoparticles of 20 nm diameter (density 1 g/cm³) in the three regions of the respiratory tract of humans and rats, calculated with the Multiple Path Particle Dosimetry model (see text).* Assumed is an inhaled concentration of 100 μg/m³ over an 8-hour exposure with nasal breathing under resting conditions. Deposition is normalized per cm² of surface area of a specific airway region.

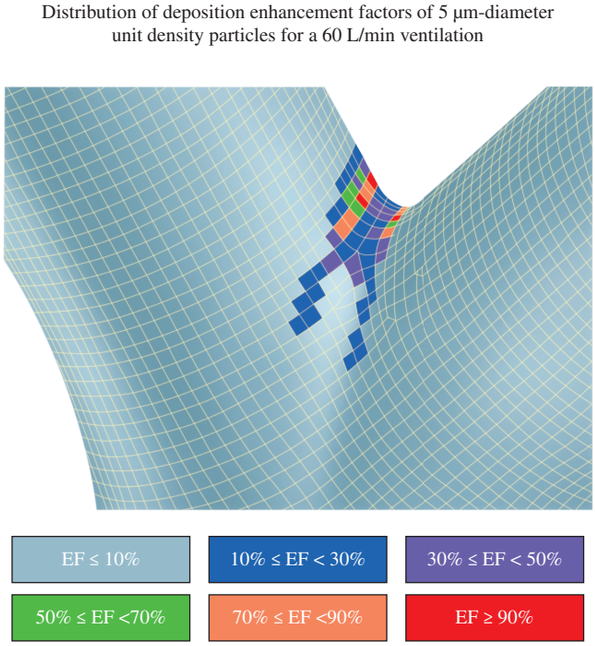

Figure 29-16. *Distribution of hotspots of deposition on carinal ridges of the bronchial region in the human respiratory tract.* The enhancement factor is largest for aerodynamically large particles, but is very low for airborne nanosized particles. (From Balásházy et al. [2003].)

only similarities but also differences become obvious: Qualitatively, size-dependent deposition fractions are similar; for example, there is a lowest point of deposition for inhaled particles in both species around the size of 0.5 μm, which is due to the fact that at this size the combined impact of diffusional displacement and gravitational settling is minimal, so they are most persistent in the air. Of interest is that—contrary to a general misconception—the smallest inhaled particles (<5 nm) are not depositing in the most distal areas of the lung, but in the upper extrathoracic region. Thus, the nasal filtering capacity is effective for both the smallest and largest particles.

Obvious differences between rats and humans are the maximum size of particles that are respirable, that is, will reach the alveolar region. In rats, this is about 5 μm aerodynamic size, in humans about 15 μm. Although these sizes are outside the range of single NP, airborne NPs occur for the most part as agglomerates, which can reach μm size equivalent aerodynamic diameters. The concept of rat versus human respirability also applies to smaller μm size particles. Even for submicron-sized particles, rat/human deposition fractions are not necessarily the same. Thus, if a rat inhalation study is designed to simulate a human exposure scenario with an aerodynamic median particle size of 5 μm, not much of the aerosol will reach the rat's alveolar region. Instead, attempts should be made to streamline the particle size for the rat study such that the deposited dose in the alveolar region is similar between the two species relative to alveolar surface area.

The deposition curves in Fig. 29-14 imply that inhaled particles of ~20 nm have similar deposition efficiencies in all three regions of the respiratory tract. However, a more judicious analysis reveals that the alveolar region actually receives the least amount of these NPs when the deposited dose is expressed per unit surface area (Fig. 29-15). The data in this figure are derived from the MPPD model, assuming an 8-hour exposure to 20 nm monodispersed TiO_2 NPs under nasal-breathing conditions for rats and humans. As can be seen, the deposited dose normalized for surface area is less than 1 ng/cm² in the alveolar region, and is highest for the extrathoracic nasopharyngeal region. This result should also serve as a reminder that realistic in vivo doses to cells of the respiratory tract are mostly orders of magnitude lower than doses that are typically applied in vitro to lung epithelial cell cultures. Moreover, the deposited dose in Fig. 29-15 had accumulated over an 8-hour exposure, which is different from a high in vitro dose rate, similar to dose rate differences between in vivo instillation and inhalation (see Fig. 29-10).

The development of deposition hotspots in the respiratory tract during particle inhalation is often cited as justification for using high doses in vitro studies (Phalen et al., 2006). These hotspots occur at the bifurcations (carinal ridges) of the upper generations of the tracheobronchial region where due to impaction more particles per unit surface will deposit compared to the average deposition per unit surface over the length of the airways (Fig. 29-16). Concentrations up to several 100-fold higher than on average in the airway may be accumulated for larger particles. However, as Balásházy et al. (2003) pointed out using computer modeling, the size of the area receiving the highest concentration is the size of square (patch) with a sidelength of only 0.1 nm, and airborne NPs are contributing to these hotspots to a lesser degree only: for a patch size of 1 mm the enhancement factor is about 30-fold for 1 to 100 nm particles. In the alveolar region where the airflow is very low, no deposition hotspots for NPs exist (Balásházy et al., 2008). This non-homogeneous deposition and formation of hotspots seems to correlate with predilection sites for bronchial carcinoma (Schlesinger and Lippmann, 1978; Balásházy et al., 2003), which is further enhanced by less effective mucociliary clearance at carinal ridges.

Respiratory Tract Clearance and Disposition of NP: Nanomaterials

Once NP are deposited in the respiratory tract, they will encounter physiological clearance mechanisms in the nasal–oropharyngeal, tracheobronchial, and alveolar region as described under "Particle

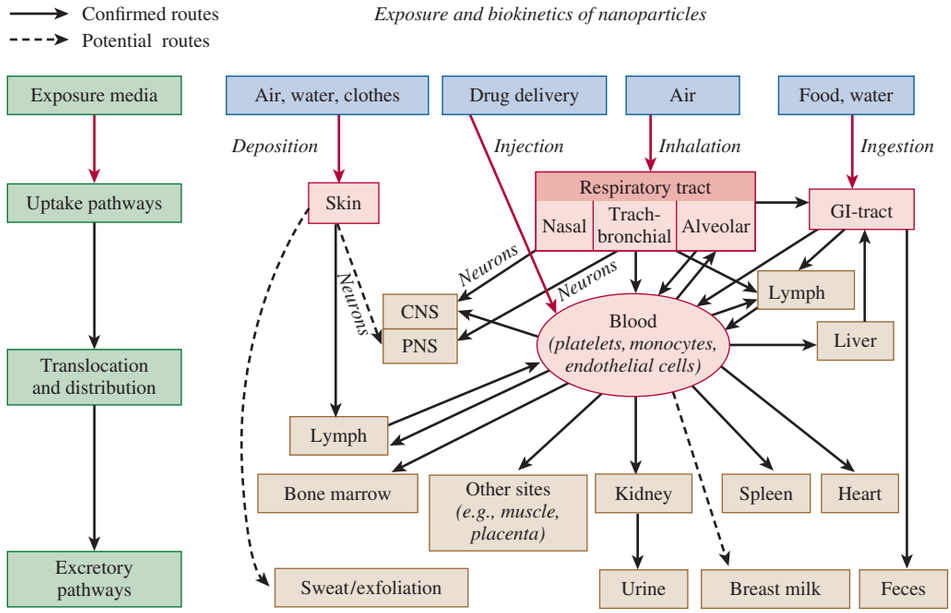

Figure 29-17. *Exposure and biokinetics of nanoparticles' routes of exposure and biokinetics (uptake, distribution, elimination) of nanomaterials.* Translocation rates in general are very low (see text). (Modified from Oberdörster et al. [2005].)

Clearance" in Chap. 15. However, there are several differences that separate NP from larger particles, as indicated in Table 29-2. Alveolar macrophages generally are attracted to deposited particles by chemotactic signals generated at the site of deposition, for example, C5 via activation of complement by particles (Warheit et al., 1988a, 1988b). Nanosized particles may be too small to generate such signal; studies in rodents with inhaled particles ranging from nano- to micro-size have shown that in vivo macrophage surveillance in terms of phagocytosis and clearance of nanosized particles is rather poor (Oberdörster et al., 2005; Semmler-Behnke et al., 2007; Geiser et al., 2008), so that deposited NP will interact with epithelial cells. Uptake into the pulmonary interstitium occurs, and there is evidence that some of the interstitialized NP reenter the airways, possibly the smaller conducting airways, from where they are cleared via the mucociliary escalator (Semmler-Behnke et al., 2007).

Translocation into the interstitium and subsequently into blood and lymph circulation distinguishes nanoparticles from microparticles. Fig. 29-17 depicts the blood compartment as a plenum from which any tissue/organ can be reached by circulating NP. However, the amount of NP translocating from the lung to the blood circulation and accumulation in secondary organs is very low, as results from rat inhalation studies with NP have shown, about 1% to 2% of the lung deposit (Kreyling et al., 2002, 2009; Semmler-Behnke et al., 2007). Long-term retention studies with radioactive iridium NPs (15 to 20 nm) have shown that clearance of NP in extrapulmonary organs following the initial accumulation is very efficient so that after 6 months, with the exception of liver and spleen, only minor amounts—below the level of detection—were still present. Liver and spleen also had decreased sharply to levels of less than 0.05% of the initial lung burden. In general, the overall pattern of long-term clearance from the lungs of rats was similar to that of microparticles with retention halftimes of 70 to 90 days. Elimination of NP from the body occurred via feces (Semmler et al., 2004) and via urine for smaller NPs (see below). Despite the low translocation rates of NP from the portal of entry to secondary organs and efficient clearance, it has to be considered that a continuous exposure may result in significant accumulation in some secondary organs. Significant efforts should, therefore, be made to design studies to assess the biokinetic behavior of ENM following relevant exposures.

Biokinetic studies have shown that organs with major reticuloendothelial system (RES) functions, such as liver and spleen, take up most circulating NP. Coating NP with PEG prevents this uptake by phagocytes and thereby the circulation time is increased, which may be desirable for medical diagnostic or therapeutic applications (Ballou et al., 2004). Other RES organs for accumulation of nanomaterials include the bone marrow and the developing organism in utero. Like the liver and spleen, the bone marrow can receive similarly high or even higher doses of blood-borne NPs (Rinderknecht et al., 2007). As a major RES organ, studies need to be designed to determine responses of stem cells in bone marrow upon interaction with ENM in vivo. A recent study in mice after administration of very high doses in drinking water of TiO_2 NP (~25 nm) for 5 days reported induction of DNA double strand breaks in bone marrow cells (Trouiller et al., 2009). The authors interpreted this finding as secondary to a systemic inflammatory response; multiple other organs also showed oxidative stress responses and genotoxicity. The authors did not attempt to determine the amount of TiO_2 in different organs, which would have strengthened the study.

Organs with tight endothelial junctions, in particular the central nervous system, will not likely accumulate blood-borne NPs, unless the tight blood–brain barrier is damaged or NP surface has been specially modified (Kreuter, 2004). For example, coating NP with the surfactant polysorbate 80 made it possible to deliver a drug loaded into NP across the blood–brain barrier (BBB), to the brain. Translocation across the BBB was facilitated via the endothelial low-density lipoprotein (LDL) receptor, and coating of the NP with ApoE-lipoprotein achieved the same result. The drug was either released to diffuse into the brain after NP uptake into the endothelial cells or via NP transport into the brain (Kreuter, 2004). In either case, the mechanism for drug delivery may be based on a "Trojan Horse" effect in which the coated NP mimic lipoprotein particles.

This underlines again the importance of protein adsorption (corona formation) for the biodistribution of NP following uptake into the organism.

Nanomaterials and the Brain

Fig. 29-18 depicts four basic translocation pathways of inhaled NP from the upper and lower respiratory tract into the CNS. In addition to the blood circulation, which does not efficiently contribute to CNS translocation because of the very tight blood–brain barrier, there is uptake into the lymphatic system—again feeding back into the blood circulation—and transport in or next to sensory neurons from the upper respiratory tract. Perineural translocation along the olfactory nerve will deliver NP into the cerebrospinal fluid (CSF), as reported by Czerniawska (1970) and Zhang et al. (2006). To what degree transport into brain tissue may be inhibited due to a cerebrospinal brain barrier needs to be assessed in further studies. The most efficient pathway of NP translocation to the CNS appears to be via olfactory sensory neurons from the nasal olfactory mucosa directly to the olfactory bulb (Oberdörster et al., 2009). The discovery of this nose to brain connection as an NP passageway goes back to early studies demonstrating this pathway for polio virus ~30 nm transport from the nose to the brain in nonhuman primates following intranasal instillation (Brodie and Elvidge, 1934; Bodian and Howe, 1941), and subsequently visualized by transmission electron microscopy (TEM), with silver-coated gold NP (50 nm) instilled intranasally into squirrel monkeys (De Lorenzo, 1970). More recent inhalation studies with insoluble carbon NP (~36 nm) and poorly soluble Mn-oxide NP (~30 nm) confirmed the olfactory nerve system as an efficient mechanism for airborne NP to reach the CNS (Oberdörster et al., 2004; Elder et al., 2006). Inflammatory responses in the olfactory bulb and several brain regions were induced by 12 days of manganese oxide exposure at concentrations that are lower than those experienced by arc welders after exposure to a mixture of nanosized particles—including manganese oxides. Other nasal instillation studies in mice, applying enormous high doses, reported oxidative stress and inflammatory responses (Wang et al., 2008a, 2008b). Results of epidemiological studies of impaired cognitive function and of neurodegenerative brain pathology associated with exposure to traffic-related particles raised the question as to whether ambient UFPs as constituents of urban air pollution may be etiologically involved (Calderon-Garciduenas et al., 2011; Weuve et al., 2012). Whether such etiological link exists is still to be investigated. The plausibility of a respective hypothesis is supported by findings that loss of olfactory function has been described as a common characteristic of neurodegenerative diseases, that is, Parkinson, Alzheimer, and Huntington disease (Moberg and Doty, 1997; Kovács, 2004; Barrios et al., 2007; Doty, 2008).

In the same study by Trouiller et al. (2009) mentioned before, the authors had also exposed pregnant mice to TiO_2 NP in drinking water for 10 days. The offspring had a higher frequency of DNA deletions in the retina when examined at 20 days of age. Due to the extraordinarily high dose of 500 mg/kg and the lack of verifying TiO_2 in fetal tissues, these results have to be interpreted with caution. Other studies evaluated exposure of the fetus to NP size-dependent translocation across the placenta in mice, with smaller quantum dots transferring more readily than larger ones (Chu et al., 2010). Takeda et al. (2009) injected TiO_2 NP subcutaneously in pregnant mice (100 µg/mouse on each of 4 days). They identified TiO_2 NP in testis and brain of the six-week-old male offspring. The authors also observed reduced daily sperm production and apoptotic cells in the olfactory bulb of these offspring. Results of this bolus-type injection study may be viewed as a proof-of-principle study for demonstrating placenta penetration because of the non-physiological mode of delivery of a high dose and high dose rate; however, the same group had reported in a mouse inhalation study with diesel exhaust the presence of UFPs in the brain of offspring and increased apoptosis of Purkinje cells in the cerebellum (Sugamata et al., 2006).

A more recent proof of principle inhalation study using concentrated ambient UFP for postnatal (day 4 to 13) exposure of mice pups found striking inflammatory effects and microglial activation and persistent male-specific enlargement of lateral ventricles (ventriculomegaly), associated with repetitive and impulsive behavioral effects (Allen et al., 2017). The authors concluded that these results indicate risk factors for autism spectrum disorder and also for other neurodevelopmental disorders.

Elimination of Nanomaterials

Elimination pathways for ENM from the body (Fig. 29-17) include mainly feces and urine. Urinary excretion is restricted to nanostructures <5.5 nm in size for metal-based NP (Choi et al., 2007), limited by the hydrodynamic diameter of the particle that may

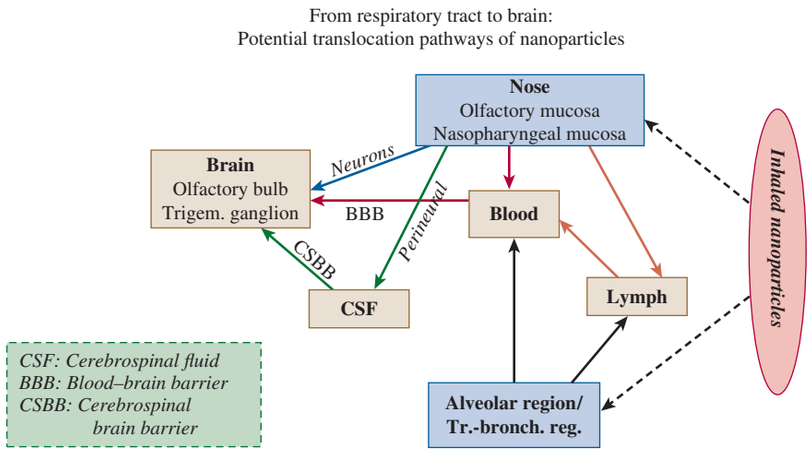

Figure 29-18. *From the respiratory tract to the brain: Potential translocation pathways of inhaled nanomaterials from the upper and lower respiratory tract.* Note that the BBB is very tight and that neuronal pathway circumvent this barrier. (Used with permission from Oberdorster, G., A. Elder, et al. Nanoparticles and the Brain: Cause for Concern? *J Nanosci Nanotechnol*. 2009;Aug:9(8):4996–5007.)

change in circulation due to protein adsorption. This general principle appears to be different for circulating fibrous structures of ENM. Singh et al. (2006) and Lacerda et al. (2008) reported that even 20 to 30 nm diameter MWCNTs with length between 0.5 and 2 μm were collected in urine of rats following intravenous application. They explain this phenomenon by a hydrodynamic lining up of nanotubes so they will pass through glomerular pores. The fecal excretory clearance pathways consist of several inputs: One is mucociliary clearance of deposited particles from the airways into the GI tract; another is via hepatobiliary clearance of blood-borne ENM via liver and bile into the small intestine. This elimination pathway is suggested by results from Semmler-Behnke et al. (2007), and it is also a well-known excretory path for heavy metals in the blood (Clarkson et al., 1988).

With regard to the CNS, no data on ENM elimination are available yet. It is conceivable that the CSF via its connections to the nasal lymphatic system (Czerniawska, 1970) and to the blood circulation could be an excretory pathway for the brain, which needs to be investigated in future studies. Indeed, Segal (2000) concluded from their review on CSF barriers that the CSF may both act as a compartment for distribution of substances to many brain regions, but also can act as an elimination route for waste products into the blood circulation because the brain is considered to have no lymphatics.

However, recent studies in mice reported the discovery of a new cleansing system in the CNS, consisting of lymph-like para-arterial and para-venous vessels in the CNS involving glia cells (Iliff et al., 2012). The authors coined the term "glymphatic system" for this clearance pathway in the brain, connecting to the CSF and clearing interstitial solutes and extra-cellular proteins and peptides such as amyloid beta. This newly discovered system, acting both as delivery (para-arterial) and also as clearance (para-venous) pathway, plays an essential role in maintaining normal CNS physiology (Achariyar et al., 2016). It may well represent also the elusive clearance route for NPs in the CNS.

Another clearance pathway of deposited ENM in the lung involves translocation via interstitium or lymph to the pleura and subsequent elimination via lymphatic openings (stomata) on the parietal pleura to mediastinal lymph nodes from where NP may enter the blood circulation via the right and left thoracic ducts. This pathway is of particular importance for fiber-shaped ENM because the size of the parietal stomata prevents efficient clearance of structures >10 μm in length. Indeed, collection of lymph from the right thoracic duct of dogs that had been dosed intrabronchially with amosite asbestos showed only fibers <9 μm in length appearing in the collected lymph (Oberdörster et al., 1988). As a consequence, the interaction of the retained longer fibers in the pleural cavity with mesothelial cells induce inflammatory and granulomatous responses and in long-term potentially mesothelioma (Donaldson et al., 2010). The following section discusses experimental in vivo data from bolus-type and of the toxicology of CNT that confirm the possibility of a mesotheliogenic response, but also caution to extrapolate directly to realistic inhalation exposures without further verification. A critical appraisal of the available in vivo study concludes this section.

CASE STUDY: MWCNT

Bolus-type Exposures

As described in the previous paragraphs, bolus-type delivery has been the preferred method of dosing to identify as a first step of the potential hazard of ENM. The advantages and disadvantages need to be considered when interpreting the results, in particular the rationale for the administered dose levels causing potential bolus-associated responses should be critically considered. Several doses covering a reasonable range, also including a positive or negative control material for ranking purposes, should be part of a well-designed study. Knowledge about actual—if available—or anticipated exposure levels should be used to justify a selected dose range. Key is a careful physicochemical characterization of CNTs with respect to their original specification (pristine state) as well as any modification due to treatment (dispersants, sonification) prior to administration. Specifically, the presence of impurities (e.g., metals, organics, and amorphous carbon) needs to be considered.

Early intratracheal instillation studies in rats and mice with SWCNTs were performed with very high doses (up to 1.25 mg/rat and 0.5 mg/mouse), causing severe lung injury with rapid persistent granuloma formation including mortality (Lam et al., 2004; Warheit et al., 2004). Doses were so high to induce even physical blockage of conducting airways. Pharyngeal aspiration of lower doses with purified SWCNTs in mice at lower doses caused interstitial fibrosis and granulomatous lesions, possibly due to the existence of large agglomerates in the administered suspension (Shvedova et al., 2005). Subsequent aspiration studies in mice confirmed these findings in mice, showing also that the responses were not affected by the metal content; however, the degree of dispersion influenced responses such that administration of the same mass dose of well-dispersed SWCNTs caused greater and more persistent responses than poorly dispersed SWCNTs (Shvedova et al., 2008; Mercer et al., 2008).

MWCNTs delivered to rats by intratracheal instillation (0.5 to 5 mg/rat) also induced inflammatory, granulomatous, and fibrotic responses; these responses were lower when the material was ground such that the length of the MWCNTs was reduced from 6 to 0.7 μm (Muller et al., 2005). Another study compared pulmonary responses to purified MWCNTs in mice when given either by instillation (50 μg/mouse) or inhalation (32.6 mg/m^3, 6 h/day, up to 15 days, estimated to result in 70 to 210 μg in the lung) (Li et al., 2007). Despite the higher lung dose following inhalation, only moderate effects were induced, whereas instillation resulted in severe inflammation and alveolar wall destruction, demonstrating a stark difference between responses induced by the two modes of dosing with the physiological inhalation exposure avoiding the high bolus-related response. As already mentioned before, the results of both the Li et al. and Shvedova et al. studies have to be interpreted with caution because of the uncertainty of the deposited doses in the lung following inhalation.

Other studies with instilled high doses (up to 1.75 mg/rat) of MWCNTs in rats reported transient inflammatory responses with persistent alveolar wall thickening (Liu et al., 2008). Transient inflammation and granulomatous responses in rats were also reported by Kobayashi et al. (2010) at lower instilled MWCNT doses, whereas Porter et al. (2010) observed a rapid and persistent fibrotic response in mice following aspiration of purified MWCNTs in mice (10 to 80 μg/mouse) which was confirmed by morphometric (lung tissue) analysis (Mercer et al. 2011). Additional evaluations of MWCNT responses in rats and mice confirmed inflammatory, granulomatous, and fibrotic responses following instillation or aspiration dosing (Han et al., 2010; Porter et al., 2010; Aiso et al., 2011).

Translocation of aspirated MWCNT to the pleura following aspiration in mice was also reported (Porter et al., 2010), including penetration into the intrapleural space of mice following aspiration (Mercer et al., 2010). A 6-hour inhalation exposure of mice to a very high concentration of 30 mg/m^3 confirmed that inhaled MWCNTs reaching the subpleural wall (space between peripheral

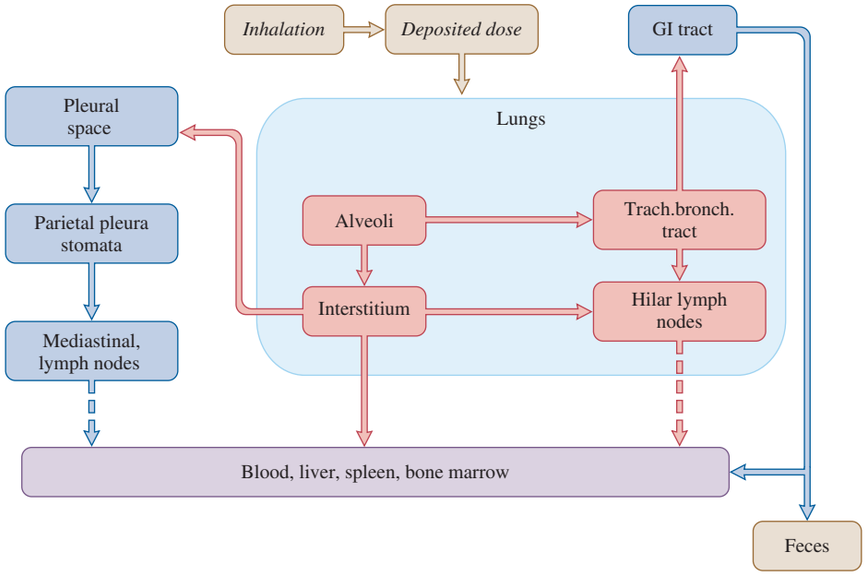

Figure 29-19. *Important translocation pathways of deposited particles in the lung that reach the interstitium are via lymphatic channels to hilar lymph nodes; or migration toward the pleura with subsequent uptake into lymphatic openings (stomata) and clearance toward mediastinal lymph nodes.* Both hilar and mediastinal lymph nodes drain into the right lymphatic duct to reach the jugular vein in the neck area.

alveoli and visceral pleura) are localized within subpleural macrophages (Ryman-Rasmussen et al., 2009a). In summary, bolus-type delivery of CNTs to the respiratory tract of rats and mice revealed induction of dose-dependent significant inflammatory, granulomatous, and fibrogenic responses; they showed also that MWCNTs can reach subpleural and intrapleural sites.

Other bolus-type studies delivered MWCNTs into the peritoneal cavity (intraperitoneal injection, or i.p.)—as a surrogate for the mesothelial lining of the pleural cavity—in order to expose mesothelial cells directly for assessing a mesotheliogenic response. Takagi et al. (2008) found, indeed, mesothelioma induction 1 year following very high intraperitoneal doses in p53 heterozygous mice, which was similar to the positive crocidolite asbestos control. A follow-up study with lower i.p. injection of 50 μg/mouse confirmed this finding (Kanno et al., 2010). Similarly, Sakamoto et al. (2009) induced peritoneal mesothelioma in rats, following high-dose MWCNT injection intrascrotally. Poland et al. (2008) also suggested an asbestos-like response after inducing mesothelial granuloma with amosite asbestos and with long, straight but not with short MWCNT 2 weeks after i.p. injection in mice. Follow-up i.p. studies showed the importance of lymphatic (Fig. 29-19) clearance of fiber structures from the pleural cavity (Murphy et al., 2011): Lymphatic stomata (Wang, 1975) in the parietal pleura with diameters of 3 to 10 μm in rodents (Shinohara, 1997) act as an effective clearance pathway for shorter fibers, whereas longer ones will be retained and induce inflammatory, oxidative stress responses progressing to mesothelioma. Such length-dependent pleural retention and lymphatic clearance was demonstrated by Murphy et al. (2011) after using i.p. injection of different types of MWCNTs and other nanotubes. Only long but not short or entangled MWCNTs caused significant mesothelial cell proliferation and granuloma formation and fibrosis. Long, rigid MWCNTs also induced malignant mesotheliomas in rats following i.p. injection: thin curved or flexible MWCNTs were less effective and the latent period for tumor induction was significantly prolonged (Rittinghausen et al., 2014).

These i.p. injection studies in rodents clearly show the potential of CNTs, specifically MWCNTs, to induce severe adverse length-dependent effects at mesothelial sites once they reach the pleural cavity. Appropriate inhalation studies in rodents need to be designed to determine the translocation of inhaled, generally highly agglomerated airborne CNTs from deposition sites in the lung to the pleura and to confirm the findings from bolus aspiration studies with well-dispersed CNTs.

Inhalation Studies

Several rat inhalation studies with CNTs in rodents have been reported (Table 29-7). Some of these were of short duration (hours to a few days), and only three were designed as subchronic 13-week inhalation studies (Ma-Hock et al., 2009; Pauluhn, 2010; Kasai et al., 2015) and two as 4-week inhalation studies (Oyabu et al., 2011; Morimoto et al., 2012). In addition, a 13-week inhalation study with carbon nanofibers has been reported (DeLorme et al., 2012). A detailed critical analysis of these four subchronic inhalation studies has been published by Oberdörster et al. (2015). All four studies were designed using three or four concentrations, with the higher concentrations causing significant inflammatory and fibrotic responses.

The authors conclude with a list of research needs to fill data gaps for improving design, analysis, interpretation, and extrapolation to humans of results of rodent inhalation studies to refine meaningful risk assessments. One data gap identified is the lack of a 2-year inhalation study. Indeed, a follow-up study by Kasai et al. (2016), designed as a 2-year multidose whole-body inhalation study with MITSUI-7 MWCNT showed the induction of lung carcinomas at concentrations of 0.2 and 2 mg/m^3 in male rats and at 2 mg/m^3 in females. No mesotheliomas were induced at any exposure concentration, and no lung tumors at the lowest concentration 0.02 mg/m^3. This well-designed and executed study clearly showing a carcinogenic response of this specific MWCNT is further discussed below.

Table 29-7

Carbon Nanotube Inhalation Studies in Rodents

AUTHOR AND YEAR	CNT	SPECIES (EXPOSURE)	AEROSOL	CONCENTRATION (mg/m^3)	DURATION	FINDINGS
Kasai et al. (2016)	MWCNT	Rats (whole-body)	MMAD 1.2–1.4 μm cyclone sieve method; dry aerosol generation	0.02; 0.2; 2.0	6 h/day; 5 days/week for 104 weeks	Significant dose-dependent increase in lung adenomas and carcinomas in male rats at 0.2 and 2 mg/m^3 No malignant mesotheliomas in males or females; ~1×10^3 nanotubes in pleural lavage at 2 mg/m^3 significant mesothelial hyperplasia and focal fibrosis of the diaphragm in male rats at 2 mg/m^3 Aggregates of MWCNTs in lungs: lung burdens were 10 μg at 0.02 mg/m^3; 152 μg at 0.2 mg/m^3; 1798 μg at 2 mg/m^3 in male rats
Li et al. (2007, 2009)	MWCNT	Mouse (whole-body)	Powder; no info. static system	32.6 (average) decreasing from 80 mg/m^3 to 1 mg/m^3 in 90 minutes	6 h/day (4 × 90 min) 8; 16; 24 day (once every other day)	Moderate proliferation and thickening of alveolar wall Lung lavage increase of protein, lactate dehydrogenase (LDH), alkaline phosphatase (ALP), and acid phosphatase (ACP)
Mitchell et al. (2007)	MWCNT	Mouse (whole-body)	Powder; mass median aerodynamic diameter (MMAD) 0.7–1 μm and 1.8 μm	0.3; 1; 5	6/day 7; 14 days	No lung inflammation or tissue damage; transient systemic immunosuppression; cytokine upregulation and oxidative stress in spleen
Sargent et al. (2014)	MWCNT alone methylcholanthrene (10 μg/g BWip alone); methylcholanthrene followed by MWCNT inhalation after 1 week	Mouse (whole-body)	MMAD 1.59 μm	4.6–4.7; lung burden = 31.2 μg/mouse	5 h/day; 15 days; follow-up for 17 months postexposure	14% of mice exposed to MWCNTs alone had lung adenocarcinomas; 22% of mice exposed to filtered air had lung adenocarcinomas; 62% of mice exposed to methylcholanthrene followed by MWCNTs had lung adenocarcinomas; 1.6% of mice exposed to methylcholanthrene alone and 9% of mice exposed to methylcholanthrene followed by MWCNTs had sarcomatous mesotheliomas
Shvedova et al. (2008)	SWCNT	Mouse (whole-body)	Powder; mass mode aerodynamic diameter 4.2 μm	5.5	5 h/day 4 days	Multifocal granulomatous pneumonia, interst. fibrosis; oxidative stress; K-ras mutation lung
Ryman-Rasmussen et al. (2009b)	MWCNT	Mouse (whole-body)	Collision jet nebulizer from suspension with pluronic F-68, MMAD ~0.16–0.21 μm	1; 30	6 hours	CNT embedded in subpleural wall and in subpleural macrophages; subpleural fibrosis; no pleural fibrosis or granuloma up to 154 weeks postinhalation
Ryman-Rasmussen et al. (2009b)	MWCNT	Mouse, OVA allergic model (whole-body)	Collision jet nebulizer from suspension with pluronic F-68; MMAD 0.714 μm	100	6 hours	MWCNT throughout lung in macrophages and epithelial cells; fibrosis in OVA sensitized mice, but not in normal mice; elevated platelet-derived growth (PDG) factor in nonsensitized mice; OVA and MWCNT act synergistically

The value of short-term inhalation studies for risk characterization can be questioned because such exposures to CNTs at realistic low concentrations are not likely to reveal certain chronic effects if long latency periods are involved. Although unreasonable, very high concentrations with short exposures may be helpful for purposes of hazard identification and toxicity ranking—which could be achieved at less cost and effort by bolus-type studies—they are not useful for deriving a no observed adverse effect level (NOAEL) or for quantitative risk assessment. Thus, beside a very costly 2-year inhalation study, most meaningful and best justified for the risk assessment process would be a subchronic multiconcentration (minimum three concentrations) study with sufficient postexposure observation. However, short-term, even one-term, exposure to a relevant concentration is very useful for dosimetric purposes when determining the biodistribution from deposition sites in the lung to secondary organs. Of course, a prerequisite is the availability of sensitive detection methods, such as radioactive labeling (Kreyling et al., 2009) or use of a nonleachable catalyst firmly attached to or embedded within the CNTs.

The choice of the mode of inhalation exposure—whole-body or nose-only—is up to the investigator. Generally, for long-term chronic exposures, whole-body is preferred because the tight confinement of rodents during nose-only exposures induces additional stress, despite careful adaptation prior to starting exposures (Pare and Glavin, 1986; Sistonen et al., 1992; Udelsman et al., 1993; Fawcett et al., 1994; Rothenberg et al., 2000). The disadvantage of whole-body exposure is the contamination of the animals' fur with aerosolized CNTs, which may lead to additional oral intake due to preening. However, the additional dose is very low, and GI-tract exposure is part of any inhalation exposure due to bronchial clearance of the deposited material.

Most of the CNT inhalation studies were performed with MWCNTs; only two used SWCNTs. Exposure concentrations ranged from 0.1 to 32.6 mg/m^3, either inhaled as one concentration only, or up to four concentrations; duration was from 6 hours to 13 weeks. Outcomes (Table 29-7) range from no significant effects to severe pulmonary inflammation/oxidative stress responses; one study reported systemic effects including cytokine and oxidative stress responses in the spleen (Mitchell et al., 2007).

In an initiation-promotion study in mice, exposure to a single injection of methylcholanthrene i.p. followed by inhalation of long, rigid MWCNTs for 15 days at 5 mg/m^3, 62% of the mice developed lung adenocarcinomas after 17 months. Only 13% of mice exposed to filtered air, 22% exposed to methylcholanthrene alone, or 14% exposed to MWCNTs alone developed adenocarcinomas (Sargent et al., 2014). Sarcomatous peritoneal mesotheliomas were also found in 9% of the mice exposed to methylcholanthrene and MWCNTs. On the basis of this initiation-promotion inhalation study, together with mesothelioma induction following i.p. (Nagai et al., 2011; Takagi et al., 2012) or intrascrotal injection (Sakamoto et al., 2009), the International Agency for Research on Cancer concluded that there was sufficient evidence for carcinogenicity of this type of long, rigid MWCNT (Grosse et al., 2014). After consideration of additional mechanistic evidence (reviewed subsequently in Kuempel et al., 2017), this type of MWCNT was classified in Group 2B as possibly carcinogenic to humans. More recently, a similar type of MWCNT was evaluated for carcinogenicity following transtracheal intrapulmonary spraying at a 1mg/rat dose for 2 weeks. After 109 weeks, lung adenomas and carcinomas and malignant mesotheliomas were induced in the pleural or pericardial linings (Suzui et al., 2016). Lung carcinogenicity of long, rigid MWCNTs was also confirmed following inhalation in rats for 104 weeks at three concentrations. The lowest concentration of 0.02 mg/m^3 did not induce a statistically significant increase in lung tumors compared to 13% at a dose of 0.2 mg/m^3 and 16% at 2 mg/m^3 in male rats (Kasai et al., 2016). The authors calculate that 1×10^9 nanotubes need to be deposited in the lungs to induce lung tumors; no tumors were induced at the lowest dose of 0.02 mg/m^3 in male rates. The total lung burdens in male rats exposed to 0.2 or 2 mg/m^3 of MWCNTs that significantly induced lung tumors were 0.15 or 1.8 mg, respectively. These authors calculate that a worker exposed to 8.5 mg/m^3 of MWCNTs for 45 years would have a lung burden of ~38 mg, which is equivalent to a lung burden of 150 μg in these male rats (Kasai et al., 2016). No mesothelioma were induced in this inhalation study. NIOSH has recommended prevention strategies including engineering controls, worker training, and use of personal protective equipment to minimize workplace exposure to CNTs (Castranova et al., 2013).

Although bolus-type delivery did result in pleural effects and translocation of MWCNT toward pleural sites as discussed before, few pleural effects were seen except pleural thickening at the two highest exposure concentrations in the 13-week inhalation studies (Pauluhn, 2010). Following inhalation of long, rigid MWCNTs for 104 weeks, the highest dose of 2 mg/m^3 induced parietal pleural mesothelial hyperplasia and focal fibrosis of the diaphragm in rats (Kasai et al., 2016). Although lung tumors were induced after inhalation of 0.2 or 2 mg/m^3, no malignant mesotheliomas were found. Only 1000 nanotubes were recovered in pleural lavage fluid and this dose was most likely not sufficient to induce mesotheliomas (Kasai et al., 2016). Movement of inhaled MWCNT to subpleural sites was observed by Ryman-Rasmussen et al. (2009a) when individual fibers and very fine agglomerates (160 to 210 nm) were generated from a liquid suspension following a single 6-hour very high concentration exposure of 30 mg/m^3. However, pleural fibrosis or granuloma did not develop up to 22 weeks postexposure. The small size of the aerosol as well as an extremely high dose may have been a factor in a deeper peripheral lung deposition. A follow-up 6-hour study by Ryman-Rasmussen et al. (2009b) with inhaled MWCNT in an ovalbumin (OVA), allergic mouse model found a synergistic effect; MWCNT alone did not induce fibrosis in nonsensitized mice. This result is in contrast to their earlier study where a 6-hour exposure to a threefold lower concentration did induce subpleural fibrosis in mice (Ryman-Rasmussen et al., 2009a). The larger aerosol size in the second study may have prevented significant deposition in the peripheral lung.

Regarding a comparison between MWCNT- and SWCNT-induced pulmonary or secondary organ effects, the only medium-term (4 weeks) SWCNT inhalation study in rats (Morimoto et al., 2012) did not observe any effect; however, estimated lung burdens were just 1.8 and 8.8 μg, about the same as the lowest concentration in the Pauluhn (2010) study with MWCNTs that also did not show any effect (NOAEL).

Critical Appraisal of CNT In Vivo Studies

Several intrapleural injection studies with MWCNTs in mice have indicated that CNTs have a mesotheliogenic potential, discussed in the previous section. In addition, intratracheal instillation studies in rats and oropharyngeal aspiration studies with MWCNTs and SWCNTs have confirmed a pulmonary inflammatory and oxidative stress-inducing potential. These results have raised concern that CNTs may represent and give rise to another case of asbestos fiber toxicity and pathology, in particular insidious because of the decades-long latency period from exposure to manifestation of mesothelioma. Controversy exists regarding the applicability of results of intracavitary injection studies for regulatory purposes. European regulations for synthetic mineral fibers exonerate those from being classified as

a carcinogen if it can be shown that the material fulfills one of the following conditions (EC Directive 97/69/EC, Nota Q, 1997):

- a short-term biopersistence test by inhalation has shown that the fibers longer than 20 μm have a weighted half-time less than 20 days, or
- a short-term biopersistence test by intratracheal instillation has shown that the fibers longer than 20 μm have a weighted half-time less than 40 days, or
- an appropriate intraperitoneal test has shown no evidence of excess carcinogenicity, or
- absence of relevant pathogenicity or neoplastic changes in a suitable long-term inhalation test.

This regulation is based on a number of experimental studies going back to Stanton et al. (1981) and Pott et al. (1987) that showed induction of tumors when different types of asbestos and persistent synthetic mineral fibers were directly injected into the pleural or peritoneal cavity. However, use of this test for regulatory purposes has not been established in the United States; the test has been criticized because of the massive doses being used leading to fibrotic reactions thereby interfering with an overwhelming physiological defense mechanisms. As to whether present European regulations will be applied to CNTs is questionable because they have been issued for man-made vitreous (silicate) fibers and the high bolus doses and associated caveats should be considered.

Still, results of CNT intracavitary injection, trans-tracheal spraying, and inhalation studies summarized in this section have defined the potential of CNTs to induce mesothelioma, depending on their dimensions, rigidity, or flexibility, and their agglomeration state. These appear to be in agreement with results from intraperitoneal injection studies, which did not show an adverse effect of short, straight MWCNTs because of effective removal by lymphatic clearance.

Obviously, given the importance of the physicochemical properties of CNTs for inducing adverse effects, it is of utmost importance to determine these properties, in particular as they appear in the airborne state at sites of human exposures, at occupational sites, or for the consumer. Adding dispersants for testing purposes will change surface properties; conceptually, inhalation studies in experimental animals for purposes of hazard identification should mimic human exposure conditions with regard to airborne size distribution. Of course, differences in respirability between humans and rats/mice have to be considered, and—if necessary—adjustments be made without use of surface altering dispersants or harsh physical treatment.

Appropriately designed multidose subchronic inhalation studies, including a longer recovery period, are essential for deriving NOAELs; results can be used as basis for deriving OELs by applying rodent/human dosimetric adjustments (Fig. 29-20). Using results from bolus-type studies is difficult and raises questions, although the national institute for occupational safety and health (NIOSH, 2011) has combined results of fibrotic responses from diverse bolus-type and inhalation studies to derive a provisional recommended exposure level (REL) of 7 μg/m^3. This REL is based on dose–response data from the available studies with bolus-type and short-term inhalation exposures and a subchronic inhalation study. Differences in lengths, use of dispersants, and impact of hugely different dose rates between the studies were not considered. NIOSH (2011) suggested, though, that the mass-based REL may not be sufficiently sensitive for detecting CNTs by air sampling and calls for research to determine the most sensitive dosemetrics.

Collectively, the available in vivo toxicological database of MWCNTs has identified a fibrogenic and carcinogenic effect

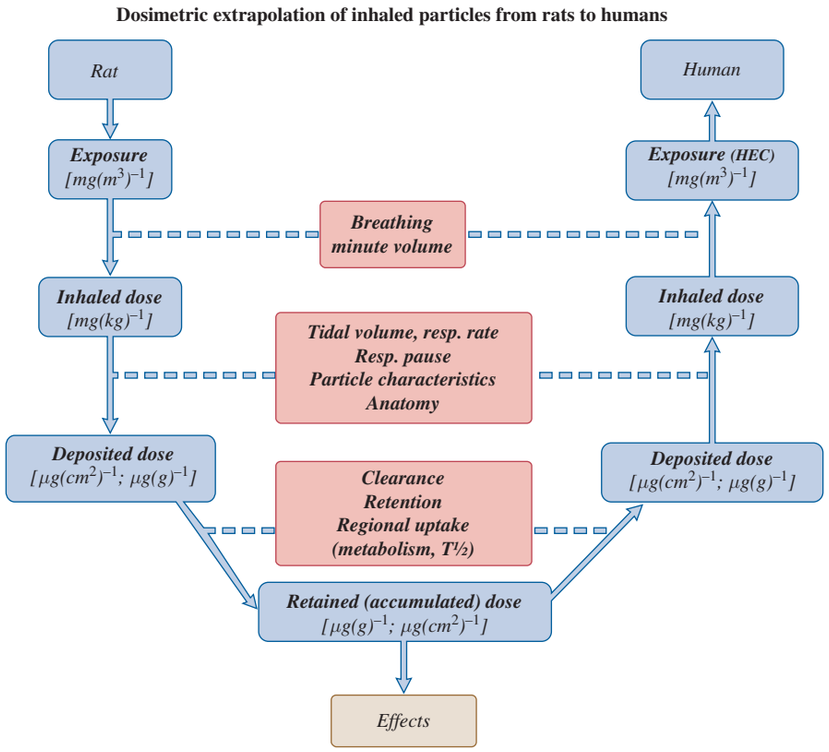

Figure 29-20. *Dosimetric extrapolation of deposition and retention in the respiratory tract from rats to humans: The concept is to achieve the same retained dose in the lungs of humans as has been found at the end of a long-term chronic inhalation study in rats.* According to the scheme above, use of a dosimetric extrapolation model for rats and humans (see text) allows to estimate the respective human equivalent concentration (HEC). (From Oberdörster [1989].)

(hazard identification). SWCNTs also appear to be fibrogenic in the lungs. The old paradigm of dose–dimension–durability for fiber carcinogenicity may also apply to CNTs: they are quite durable (though some studies have now reported degradation of carboxylated SWCNT by peroxidases in vitro, see below), and their dimensions in terms of length, diameter, and agglomeration/entanglement appear to be important for pulmonary effects. Of course, other properties (chemistry, surface reactivity) may play a role as well. There is an obvious and urgent need to perform additional long-term (subchronic to chronic) inhalation studies to assess the carcinogenic potential of multiple types of CNTs and carbon nanofibers and derive protective OELs (Kuempel et al., 2017).

Biological Degradation of Carbon Nanomaterials CNTs have been generally regarded as stable nondegradable materials, which has important implications for long-term health effects following inhalation into the lungs (Donaldson et al., 2006). Recently, however, SWCNT degradation has been observed in acellular assays that simulate the phagolysosome of macrophages, but only if the tubes have been surface carboxylated, which introduces collateral defects in the side walls (Liu et al., 2010c). Carboxylated tubes are also susceptible to biodegradation by exposure to hydrogen peroxide and horseradish peroxidase (Allen et al., 2008, 2009; Kagan et al., 2010) or hypochlorite and the mammalian enzyme myeloperoxidase (Kagan et al., 2010). Kotchey et al. (2011) also reported that graphene oxide, but not reduced graphene oxide, is susceptible to oxidative attack by hydrogen peroxide and horseradish peroxidase. These observations may enable design of safer carbon materials (Yan et al., 2011) that are potentially biodegradable in order to minimize adverse environmental and human health impacts. However, degradation of CNTs in vivo is still to be confirmed.

TOXICITY TESTING

Although numerous in vitro and in vivo studies have reported toxic effects of different ENMs, results are often conflicting and hazards are overstated due to poor understanding and knowledge about the appropriateness of applied doses and concentrations and their relevance to realistic exposures. This issue will be further discussed later. A conceptual testing paradigm is shown in Fig. 29-21. In order to perform risk assessment or to derive OELs, exposure and hazard data are required. To identify and characterize a hazard, in vitro and in vivo studies will be useful, and results should be derived via well-designed dose–response relationships. Key considerations for designing such studies include careful physicochemical characterization of the ENM to be tested, justification of the method(s) of dosing, selection of target cells, tissues or animal species, and appropriate endpoints. Reference materials may also be included in order to rank unknown ENMs against a known positive and/or negative control. Whereas in vitro data alone permit toxicity ranking, appropriately performed in vivo studies (using inhalation when dealing with airborne materials) will allow a full risk assessment because exposure and dosimetric extrapolation to humans can be performed. In the long term, in silico studies may be developed to assess a hazard, and in even a more distant future to predict human risk. Ideally, knowledge about anticipated human exposure would be necessary to inform both animal exposure studies as well as in vitro dosing.

In vivo animal studies obviously do not generally predict human exposures: the lower loops in Fig. 29-21 refer to dosimetric correlations between in vitro/in vivo and in vivo animals/in vivo humans, going in both directions with the goal to (a) inform the design of in vivo animal studies using available human exposure data, and (b) use exposure–dose–response information from animal studies to compare with human data. The upper one-directional animal-to-human loop refers to extrapolating effects and mechanisms from relevant (based on dosimetric relevancy) animal studies to humans, with the goal to be predictive for deriving "safe" exposure levels or OELs; thus, an animal study can be used to predict human equivalent exposure concentrations or OELs. An example for this approach is the recent subchronic rat inhalation study with MWCNT by Pauluhn (2010).

The following paragraphs focus on concepts and results of in vivo experiments as basis for use in the risk assessment process using as example CNTs. However, a need for in vitro studies should be stressed as far as uncovering underlying mechanisms of effects

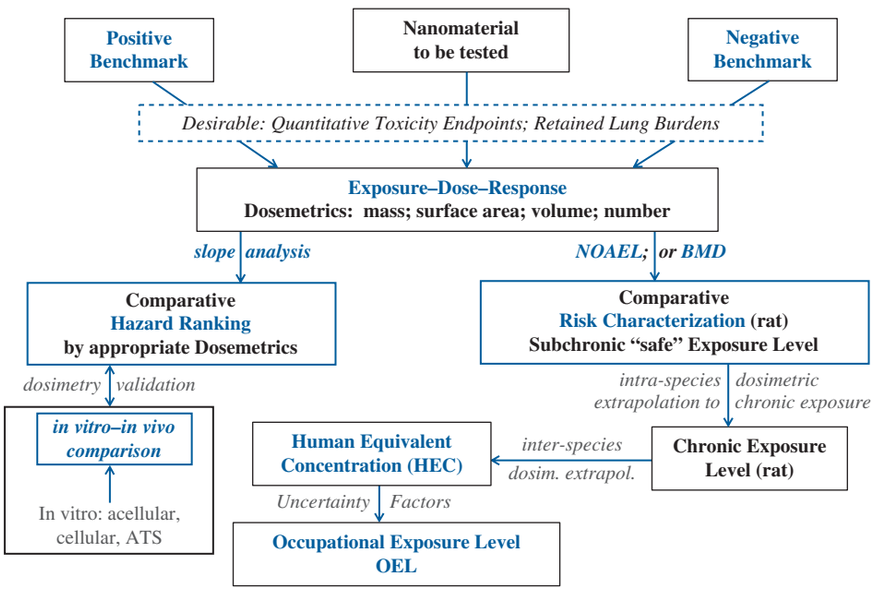

Figure 29-21. *Approach for comparative hazard and risk characterization of inhaled nanoparticles based on subchronic (3 months) rat inhalation studies.* NOAEL: no observed adverse effect level; BMD: benchmark dose; OEL: occupational exposure level; ATS: alternative testing strategy. (From Oberdörster and Kuhlbusch [2018]).

are concerned, provided that the caveats pointed out above are considered. In addition, despite these limitations, in vitro studies are useful for toxicity ranking of nanomaterials for the purpose of hazard identification (Rushton et al., 2010). In contrast, the design of in vivo studies allows the full evaluation of exposure–dose–response relationships, which is necessary for the process of risk assessment (Fig. 29-21).

Some important points should be considered when designing exposure–dose–response studies with CNTs in experimental animals. The major exposure route for CNTs to be expected is via inhalation at manufacturing sites and during distribution and usage (handling, refilling, disposal), although ingestion and dermal exposures also occur but have not received as much attention (Fig. 29-17). For medicinal applications, injection is an important route of exposure requiring specific awareness with respect to assuring desired beneficial (pharmacological) outcomes yet avoiding undesirable (toxicological) responses (Kolosnjaj-Tabi et al., 2010). For example, Yang et al. (2010) concluded from their studies with SWCNT that the desired pharmacological target organelle for drug delivery by SWCNT are the cell lysosomes, whereas the mitochondria are the target organelles for SWCNT toxicity. These aspects will not be discussed further.

In Vitro Dosimetry

The importance of dose rate for bolus-type delivery of ENM in vivo vis-à-vis inhalation has been stressed in previous sections. As most ENM toxicity studies are performed using in vitro assays, which are generally short term, dosing-related questions are highly relevant. Teeguarden et al. (2007) pointed out that the dose received by the cell is a function of colloidal dynamics or "particokinetics" in the culture medium governed by diffusion and settling phenomena, which in turn is governed by particle and media properties that include particle size, agglomeration/aggregation state, shape, density, and charge. This is very different from chemicals dissolved in culture medium and requires a thorough evaluation of particle dosimetry in vivo. At equal mass concentrations in the medium, the magnitude of the cellular dose of ENM will differ significantly from those implied by the media concentration. This can give rise to significant misinterpretation of responses and is likely to contribute to differences in results between different laboratories. For example, particles of the same material but of different sizes will settle onto cells in culture at different rates; and particles of the same size but different densities will also settle differently so that the time for particles to reach the cell layer at the bottom of a dish can vary widely. Similar to the aerodynamic behavior of airborne particles, the hydrodynamic behavior in culture medium expressed as their transport velocity shows a minimum of movement for intermediate sizes where the combination of gravitational settling and diffusional movement is lowest.

Fig. 29-22 illustrates the different mechanisms that determine the in vitro particle kinetics for particle sizes from 1 nm to 1000 nm (Hinderliter et al., 2010). A typical U-shaped form depicting faster transport at both ends of the range of sizes and a slowest transport for particles around 20 to 60 nm is the result of the competing forces and particle and media characteristics. Temperature, mixing, and advection also add to the complexity of particle movement in the media. Teeguarden's group developed an In Vitro Sedimentation Diffusion and Dosimetry (ISDD) model for predicting the in vitro behavior and cell doses of particles. Fig. 29-23 shows the results of example calculations from this model. It indicates that for large TiO_2 particles (500 nm), the dose received by the cells in a dish with 3.1 mm media height is very fast. In contrast, 30 and 50 nm particles have a long deposition rate; only 50% of the media dose has reached the cells by

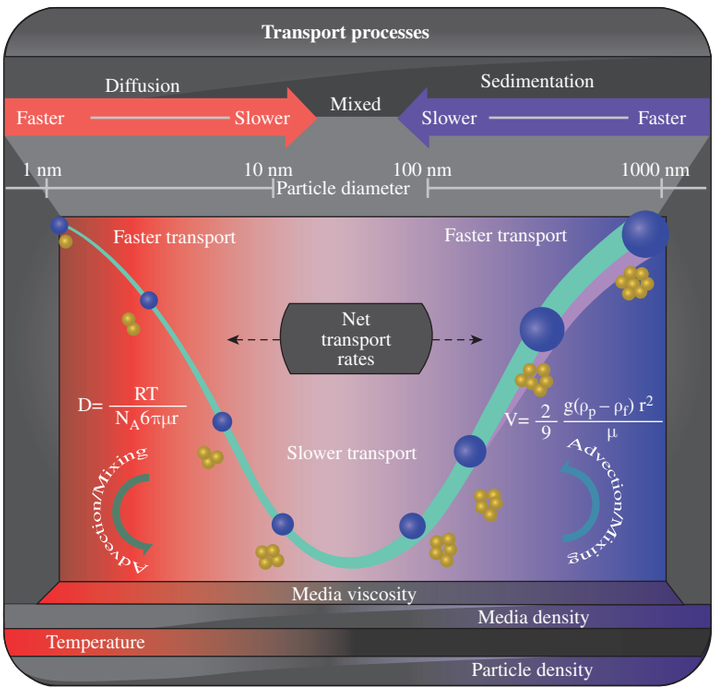

Figure 29-22. *In vitro sedimentation, diffusion, and dosimetry (ISDD) model: particle transport/deposition processes for in vitro systems.* (See text.) (Reproduced with permission from Hinderliter et al. [2010].)

24 hours. TiO_2 NP sizes in between still have not reached the full dose by 24 hours, whereas 200 nm TiO_2 NP are fully settled by 10 hours.

Further advances in in vitro dosimetry have been reported by DeLoid et al. (2015, 2017), using computational fluid dynamics and their new distorted grid (DG) model to estimate delivered dose-metrics. The authors state that these advanced models provide practical and robust tools for obtaining accurate dosemetrics and concentration profiles across the well, and that the DG model allows rapid modeling.

Results of the ISDD shown in Fig. 29-23 and DG prediction have to be verified by experiments. The value of these models lies in the clear separation between exposure (concentration in the cell medium), the deposited dose on the cell surface, and—depending on cellular uptake—the cellular dose. These doses can be expressed by different metrics: mass, number, or surface area of the nanomaterial. Knowledge about the time to deposit a certain dose allows to consider dose rate as a determinant for responses, as was discussed for in vivo exposures (Fig. 29-10). In vitro dosing is often perceived as a bolus-type delivery, similar to in vivo instillation or aspiration studies. However, as the results in Fig. 29-23 show, in vitro dosing with NP is not necessarily equivalent to an instantaneous bolus. The ISDD model allows to express the deposited dose per unit cell surface area of cultured epithelial cells of the respiratory tract and thereby (*i*) compare responses to the same in vivo dose per unit cell surface (based on MPPD model, Fig. 29-15), (*ii*) use in vivo derived doses from a given exposure concentration to design in vitro studies that include realistic doses, and (*iii*) use in vitro dosimetry results and response to verify in vivo. Likewise, doses applied in vitro to cells from secondary organs (e.g., CNS and bone marrow) can be estimated by the ISDD and DG model and better justified by results from in vivo biokinetic studies with respect to doses distributed to these secondary organs. An important difference, however, between in vivo inhalation and in vitro cell exposure is the pristine state of inhaled nanomaterials, whereas for in vitro exposures nanomaterials are either treated with dispersants to separate the particles and achieve spatially uniform dosing, or else culture media constituents (serum proteins) will adsorb to the NP surface to aid in their dispersion. Surface modification is known to affect responses of ENM (Haniu et al., 2011), and this possibility needs to be considered when designing and interpreting in vitro results.

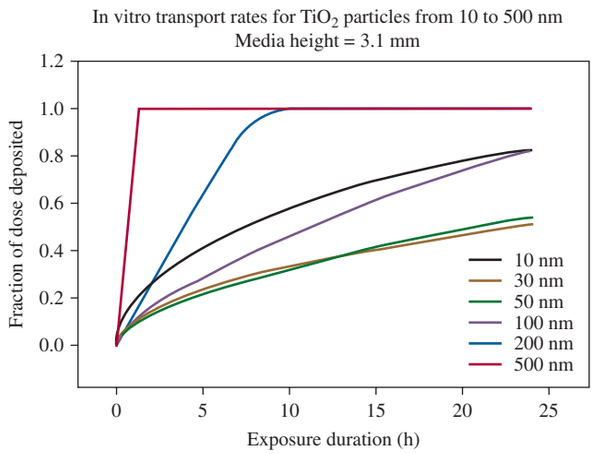

Figure 29-23. *In vitro sedimentation, diffusion, and dosimetry (ISDD) model: prediction for in vitro transport rates for TiO_2 particles from 10 to 500 nm, assuming a media height in the culture dish of 3.1 mm.* (Reproduced with permission from Hinderliter et al. [2010].)

An alternative in vitro methodology that avoids pretreatment of NP with surfactants or proteins prior to testing is exposure via an air-liquid interface (ALI) system (Holder et al., 2008; Savi et al., 2008; de Bruijne et al., 2009; Lenz et al., 2009; Volckens et al., 2009; Tang et al., 2011; Xie et al., 2012). Respiratory tract epithelial cells are grown on porous culture cell inserts and exposed to NP generated the same way as done for in vivo inhalation studies. Before exposure, culture medium is withdrawn so that only the basal cell surface is in contact with the medium, and deposition of the aerosolized NP on the apical cell surface simulates realistic in vivo inhalation exposure. Various nano aerosol chamber devices have been developed for short or longer, repeated exposures of lung target cells at the ALI (Loret et al., 2016; Geiser et al., 2017). Comparative results between conventional in vitro and ALI exposure seem to confirm the apparent advantage and greater sensitivity of the ALI system (Holder et al., 2008; Volckens et al., 2009). However, transition of cell cultures from growing in monolayer to the ALI system for exposure is likely to cause changes in gene expression, which needs to be considered using appropriate control groups (Ross et al., 2007). Other alternative exposure models for inhalation nanotoxicology include precision-cut rat lung slices (Sauer et al., 2014) and acellular human three-dimensional lung scaffolds (Wagner et al., 2014). Additional non-animal epithelial barrier models are being developed for evaluation of lung, intestinal, and skin toxicity (Gordon et al., 2015) as static or microfluidic platforms (Blume et al., 2015; Mahto et al., 2015).

Predictive Toxicology

The NNI developed a comprehensive Environmental, Health, and Safety Research Strategy (NanoEHS research; NNI, 2011) in which urgent research needs for nanomaterial measurements, human exposure assessment, human health, environmental health, risk assessment and risk management methods, and for the input of informatics and modeling for NanoEHS research are discussed. This initiative of the U.S. Government's interagency program for coordinating research and development and for enhancing communication and collaborative activities in nanoscale science, engineering, and technology emphasizes the NAS risk assessment paradigm (1983) as the basis for NanoEHS research. As illustrated in Fig. 29-21, data about hazard and exposure are key for the risk assessment process. Critical elements for hazard identification based on toxicity testing of ENM are detailed information about their physicochemical properties prior to any experiments, the selection of appropriate target cells, validation of in vitro assays in terms of correlation and relevancy to in vivo results, the inclusion of biokinetics in the design of in vivo studies, and the inclusion of realistic doses in the design of dose–response in vitro and in vivo studies. Biokinetic information is crucial for identifying potential secondary target organs based on significant accumulation of ENM. In order to determine relevant doses, information about exposures occurring at anticipated real-world exposure scenarios, either measured or estimated, is essential. With this information, exposure–dose–response (in vivo, rodents) and dose–response (in vitro, target cells) relationships can be established to both characterize a hazard and assess a risk (see below). In terms of toxicity ranking, it is desirable to include reference materials in the study design so that a hazard can be expressed relative to a positive (high hazard) or negative (low hazard) control ENM. Mechanistic information discovered through in vitro assays will further aid in the characterization of hazard, provided that the mechanism is operative at relevant doses/concentrations. High-dose and high-dose rate-induced mechanisms may not be considered relevant and may give rise to improper classification. An awareness of dosimetry-related aspects

is of highest importance (Fig. 29-21) for the risk assessment process, which often gets lost or is ignored because of a misconception of risk being analogous to hazard. Risk is a function of hazard and exposure, and neither aspect alone can determine risk.

The immediate goal of ENM toxicity testing is hazard characterization and the establishment of respective predictive tests. These should ideally be based on validated in vitro studies, for example high throughput in vitro assays, so that ethically controversial animal studies can be replaced if they only serve the purpose of hazard identification. A distant goal is the use eventually of in silico models. International workshops are trying to build a consensus among multiple stakeholders for alternative testing strategies for ENMs (Nel et al., 2013; Stone et al., 2014). However, at present, animal studies are still indispensable for obtaining crucial information about long-term effects of ENM and obtaining results for risk assessment. For example, available data from subchronic (3 months) inhalation studies (Ma-Hock et al., 2009; Pauluhn, 2010; DeLorme et al., 2012; Kasai et al., 2015) provide crucial information for deriving a NOAEL or lowest observed adverse effect level (LOAEL) that can be used for dosimetric extrapolation of OELs for humans.

Fig. 29-20 depicts a conceptual approach for deriving a human equivalent concentration (HEC) from results of a long-term rat inhalation study. The HEC is based solely on the equivalency of the retained dose, expressed per unit mass, or epithelial surface area of the lung. The retained dose can be expressed by different metrics, for example, rather than using the mass of ENM, as is conventional; the surface area or even the number of particles might be used. Pauluhn (2010) used the metric of particle volume retained in alveolar macrophages to estimate an OEL from the experimentally found NOAEL in a 3-month rat inhalation study with MWCNT. As was done in that study, it is highly desirable that the design of a rat study includes the measurement of the retained lung burden; if this is not available, the retained dose can be estimated using a particle deposition and retention model with inputs of rat-specific breathing and airway parameters and the aerosol characteristics of the ENM used in the rat study. The same aerosol characteristics and human-specific airway and breathing parameters as inputs to a human model are then used to determine the HEC. It should be noted that this dosimetric extrapolation should not necessarily imply that the response in humans is the same as in rats. Differences in species sensitivity may require the use of an additional safety factor. The advantage of using the retained dose as the basis is that other particle size distributions specific to human exposures at a workplace can be used instead of the rat aerosol (Oller and Oberdörster, 2010).

Development of a Set of Screening Tools that Reflect Important Characteristics or Toxicity Pathways of the Complex Systems Described Above In 2013, a committee of the National Academy of Sciences undertook an assessment of research progress on environmental health and safety aspects of ENMs (National Research Council, 2013). A major focus of the committee's report was to provide general guidance on research strategies for implementing hazard identification methods and studies for a variety of ENMs. This includes a critical need for developing reliable and validated tools to identify and confirm toxicity pathways of complex systems and address mechanistic issues. This is important because of the necessity for developing a set of reliable and validated screening tools which is paramount for reproducible testing of diverse nanoparticle types. In addition, toxicity results obtained from a variety of in vivo studies often have limited value for determining relevant health hazards, in large part because toxicological studies with ENMs are conducted at much higher doses than might be present from real-world exposures; or at best, they might reflect a short-term toxicological response. Time-course experiments would better simulate potential effects following exposures to nanomaterial types.

Alternatively, given the limitations of animal testing going forward—and with a greater resistance to conducting in vivo experiments, the applications of a spectrum of in vitro investigations could provide some useful mechanistic insights into toxicity pathways; however, several shortcomings to in vitro methodologies need to be addressed. Optimizing the relevance of in vitro studies to real-world toxicity considerations should require the utilization of experimental designs that necessitate dose–response behavior over a full range of doses, and should also require the duration of exposure using relevant cell-types (focusing on the route of exposure regimens) including time-course evaluations, concomitant with comparisons and validation with corresponding in vivo systems.

To summarize the suggested framework and research strategy, implementation of the following considerations would significantly improve the methodology for development of reliable and validated screening tools:

1. Rigorous physicochemical characterization of nanoparticle types and behavior through the life cycle
2. Dose–response characterization and careful attention to reliable dosimetry at relevant human exposure levels
3. Particularly for in vitro studies selection of relevant cell-types and cell models that reflect the route of human exposures
4. Time-course assessments that span acute to chronic exposure durations
5. Application of proper benchmark controls to improve interpretation of toxicological outcomes (National Research Council, 2013; Hussain et al., 2015)

DESIGNING ALTERNATIVE IN VITRO METHODS FOR SCREENING PULMONARY TOXICITY OF FINE AND NANOSCALE PARTICLES

The development of reliable and predictive aerosol-based in vitro lung toxicity assays for screening particulate/nanoparticulate materials might (in the future) limit the need for animal testing, particularly during the early phases of hazard evaluations. Additional benefits would include an enhanced capacity to screen several compounds during the early phases of product development using cost-effective and validated in vitro assays. In addition, reliable hazard data developed from these tests could serve as a bridge to the subsequent implementation of longer-term particle inhalation studies, thereby obviating the need for conducting acute (in vivo) toxicity studies, and significantly reducing the numbers of test animals. These goals are also consistent with the visions of the National Academy of Sciences—Toxicity in the 21st Century Committee which advocated a transformative paradigm shift in implementing safety studies by providing greater abilities to screen chemical hazards at various life stages; to reduce testing costs, and use fewer animals, and to develop a robust scientific basis for assessing health effects of environmental agents.

As described earlier, the paradigm for these studies must include the following aspects: (1) dose–response studies—particularly to determine the slope of the toxicity curve; (2) address the shortcomings/problems of static conditions of in vitro models vs. the dynamic conditions of in vivo effects; (3) the need for longer-term in vitro models—in order to assess a time-course response; (4) the questions

of dose equivalency for estimating the effects of in vitro vs. in vivo exposures; and (5) the need for positive and negative benchmark materials—in order to adequately interpret the results of a particular study—and for purposes of ranking/grouping. At the present time, it seems that only hazard characterization (as the first step in the Risk Assessment Paradigm) can be adequately achieved utilizing current in vitro methodologies.

Unfortunately, the accuracy of predictive results from currently conducted in vitro lung toxicity screening studies has generally been unreliable (Sayes et al., 2007). Previously published results of comparative lung toxicity studies with identical particle-types comparing submerged in vitro cell culture systems vs. in vivo (inhalation and instillation) techniques has demonstrated a lack of convergence between in vivo and in vitro effects using these cell culture methodologies. The toxicity studies used as barometers focused on similar endpoints (e.g., inflammation and cytotoxicity biomarkers) as representative indices for comparative purposes.

The lung is a complex organ system comprising many different cell-types (i.e., types I and II alveolar epithelial cells, macrophages, interstitial cells, vascular cells, etc.) (see Chap. 15); thus, the pulmonary microenvironment and the complex interactions in the lung which occur following inhalation and subsequent deposition of particles are difficult to simulate when employing in vitro techniques. In addition, numerous studies have reported in vitro toxicity results using only single cell-types (e.g., A549 lung epithelial cells—*or* lung or peritoneal macrophages) (National Research Council, 2013). However, these efforts generally represent simplified models and ignore the complex interactions in the lung microenvironment that occur following exposure to aerosols of particles, bacteria, etc. Recently, more complex in vitro systems are being developed, which can, in part, better simulate particle phagocytosis, an important aspect in the simulation of lung defense responses to particles (Hussain et al., 2015). The development of such in vitro techniques will better facilitate (and hopefully expedite) the transition from the current animal-based inhalation testing system to one that is based primarily on human cell lines and in vitro assays. Such reproducible, accurate, and validated cell-based in vitro screening assays for assessing pulmonary and genetic toxicity will have important benefits (i.e., screening more compounds in a faster, more reliable, and less expensive manner) and may provide experimental designs to address mechanistic questions.

In an attempt to improve the efficacy of an in vitro methodological approach, a number of steps have been designed to better simulate the physiology of the distal lung microenvironment, concomitant with the implementation of an aerosol exposure system. Accordingly, this transition from a traditional "submerged" cell culture system to a more physiologically relevant ALI cell culture system, using Transwell® Permeable Support devices (microporous membranes), is useful for providing and maintaining pulmonary cell co-cultures (of rat lung epithelial cells and alveolar macrophages) and exposing the co-cultures to particulate aerosols in a humidified atmosphere.

Many fundamental issues require consideration for optimization when facilitating a transition from an animal inhalation toxicity set-up to an in vitro aerosol pulmonary toxicity study. These considerations include, but are not limited to, the following actions:

- Determining the cell-types to be used in a co-culture system—to better simulate the lung microenvironment
- Transitioning from primary cell types collected from animals to immortalized cells derived from cell lines and tested for biological functionality
- Determining the number or ratio of lung epithelial cells to alveolar macrophages in a co-culture plate
- Determining the aerosol generation method for particles/nanoparticles and appropriate and reproducible and quantifiable dosemetrics to be utilized for particle inhalation deposition assessments and for comparisons of results of one study to another
- Demonstrating reproducibility for particle generation studies by measuring particle deposition on filters—and choosing appropriate filter-types and measurement methods to ensure validation of results
- Deciding on the appropriate endpoints for assessing lung toxicity parameters, which can be benchmarked against in vivo results on the same particle-types
- Validating effects, doses, and mechanism with in vivo test!

Three additional key experimental design features of a newly developed in vitro system should include:

- Time-course protocol to assess the sustainability of any measured response
- Exposure-dose–response assessments
- Utilization of benchmark particulate control test materials, in order to develop a frame of reference for better interpretation of results

Based upon these challenges, one might be able to successfully transition from a submerged cell culture system to an ALI system, for providing co-cultures (of rat lung epithelial L2 cells and NR8383 alveolar macrophages) applicable to in vitro cell exposures and toxicity assays. This more complex in vitro system can, in part, simulate particle phagocytosis and inflammation, important aspects in the assessments of lung defense responses to particles. A temperature- and humidity-controlled in vitro cell exposure chamber—the Nano-Aerosol Chamber for In Vitro Toxicology (NACIVT) system—has been optimized to host and expose the epithelial–macrophage co-cultures (n=24 samples) to aerosolized particulate atmospheres at the ALI. Particle atmospheres are generated from a source chamber prior to delivery to the NACIVT system at approximately 0.6 L/min (i.e., to each cell sample at ~25 mL/min). Particle concentration (mass/volume) and aerosol size (MMAD) are sampled gravimetrically from the source chamber while particle deposition is measured by gravimetric analyses collected on filters in the NACIVT system. Cell metabolism/cytotoxicity assays (e.g., XTT/Lactate dehydrogenase [LDH) assays) and cytokine (e.g., IL-6) release assay have been developed and modified for use to assess toxicity/inflammatory endpoints. The XTT assay is a colorimetric assay designed to assess cell viability as a function of cell number based on metabolic activity.

Read Across—Nanogrouping

As more new nanomaterial types are being produced and entering commerce, the importance of adequately testing and assessing the hazards and potential risks of these particulates becomes critical. Of course, there is insufficient time and adequate funding to thoroughly evaluate the hazards of many of these new materials in vivo. Moreover, the trend away from animal testing makes the necessity for developing a new strategy for hazard evaluation critically important. One recently proposed practical strategy for assessing potential hazards of nanoparticles involves the grouping of similar particle-types, to streamline testing for regulatory purposes. The conceptual design for this strategy is to group nanomaterials for assessment that are similar or complementary in physicochemical characteristics. Recently, the European Centre for Ecotoxicology and Toxicology of Chemicals Task Force (ECETOC) has proposed a methodology for the critical appraisal of existing concepts for the groupings of nanomaterials. These would include the properties

and biophysical interactions of nanomaterials, specific types of use and exposure, uptake and kinetics, as well as possible early and apical biological effects (Arts et al., 2014). Subsequently, the group proposed a decision-making framework for the grouping and testing of nanomaterials (Arts et al., 2015). This process was designed to cover all relevant aspects of a nanomaterial's life cycle and biological pathways. The authors developed four (general) main nanogroups of materials for testing considerations. These included the following groups: (1) soluble nanomaterials; (2) biopersistent high aspect ratio nanomaterials; (3) passive nanomaterials; and (4) active nanomaterials. The proposed grouping was designed to provide a hazard and risk assessment tool and strategy that conceivably could be tested and ultimately contribute to the sustainable development of nanotechnological products.

In a subsequent publication, this proposed methodology was implemented by developing case studies for putting into practice, the decision-making framework for the grouping and testing of nanomaterial groups (Arts et al., 2016). Per the authors, case studies covering the following nanomaterials were implemented: carbonaceous nanomaterials, metal oxide and metal sulfate particulates, amorphous silica and organic pigments were subjected (with limitation) to the decision-making framework for the potential grouping and testing of nanomaterials. The authors initially outlined two (physicochemical) tiers that relied exclusively on non-animal testing methods, followed by a third testing tier, from which data from rat short-term inhalation studies were evaluated per the four groups outlined in the previous paragraph. To summarize, the authors concluded that the utility of this grouping strategy for nanomaterial hazard assessment was confirmed (with limitation). Of course, this methodological strategy, as well as hazard and risk results for nanomaterial-types, will require confirmation and substantiation by independent investigators and research groups, but this testable concept represents an idea for organizing the testing and evaluation of new or untested nanomaterial-types, without the painstaking, time-consuming, and expensive route of individual testing of new and current products in commerce, to which consumers will be exposed.

Transition, Human—Eco-nanotoxicology

The goals of nanotoxicology are to identify and characterize a hazard of ENMs for purposes of risk assessment for humans and the environment, and this requires a highly multidisciplinary team approach, covering expertise in toxicology, biology, chemistry, physics, material science, geology, exposure assessment, PBPK and fate and transport modeling, and medicine is necessary to develop: testing strategies, establish toxicity ranking, determine "safe" exposure levels, and derive preventive exposure guidelines. As depicted in Fig. 29-24, exposures throughout the life cycle of ENMs, from their source to their disposal, have to be considered. Dispersion and intermediate transformations in air, water, food, and soil are important modifiers of ENM–receptor interactions. Identifying underlying mechanisms of such interactions will aid in assessing risk and establishing preventive measures. Developing predictive models is a distant goal for both human and eco-nanotoxicology.

ECOTOXICOLOGY OF ENMS

Environmental Uses and Exposures to Nanomaterials

As with many chemicals in the marketplace, it is estimated that a portion of the nanomaterials used in industry and consumer products will enter the greater environment during some part of their life cycle, either through waste during production or through product use. The exponential increase in use of ENMs in a multitude of industries and consumer products has been documented by the Woodrow Wilson Center's project on Emerging Technologies, which as of March 2011 estimated that self-identified nanomaterial products had grown from 54 to over 1300 in 5 years. This list likely underestimates the number of uses of nanomaterials as it only includes products easily identified as containing nanomaterials and does not include other known uses of nanomaterials, including industrial catalysts, wastewater treatment, in addition to environmental cleanup technologies and pesticides, which would directly place nanomaterials into the environment. Most of the uses identified are in cosmetics, clothing (where nanomaterials are often added for antimicrobial and antiodor functions), personal care products, and sporting goods. The most common nanomaterials included in these products are silver and carbon nanomaterials. Other chemicals used in personal care products, cosmetics, and clothing have been found to wash into the wastewater treatment system and end up in the aquatic environment either directly from the treatment facilities or through land applications of biosolids from wastewater treatment plants. It is anticipated that some of the nanomaterial components may have the same fate, and indeed a few documented cases indicate this may be possible (Wang et al., 2012) but a majority of the estimates of potential environmental release of these chemicals is from modeling based on data from other compounds without regard to specific properties of nanomaterials compared to their bulk counterparts (Mueller and Nowack, 2008; Gottschalk et al., 2009, 2010). These studies estimate that concentrations in the environment can range from ng/L to μg/L, with many agglomerating into larger than nanosized units and much of the NP mass binding to solids and removed into biosolid waste. However, despite these removal potentials, it has been shown that NPs can be emitted through the wastewater process in the NP size range in significant quantities (Westerhoff et al., 2011).

Nanomaterials directly applied to a particular ecosystem, such as those for cleanup of environmental toxicants or as part of a pesticide formulation may also lead to exposures. Nanoscale zero-valent iron and titanium dioxide are currently being evaluated as a removal technology to treat groundwater systems and some surface water or soil systems for metals, arsenic, organic chemicals such as chlorinated solvents, polychlorinated biphenyls (PCBs), and benzenes (Elliott and Zhang, 2001; Chen and von Mikecz, 2005; Quinn et al., 2005). Poly(ethylene) glycol–modified urethane has been proposed for the sequestration and enhanced bioavailability for degradation of organic contaminants (Tungittiplakorn et al., 2005). Pesticide formulations containing carbon-based nanomaterials and others have been sent to the U.S. Environmental Protection Agency (EPA) for evaluation and are assumed to be in development.

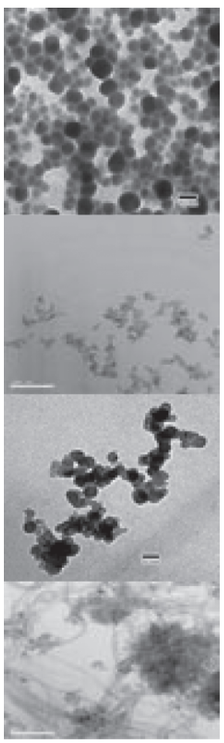
Figure 29-24. *Measures of ecological effect at the different levels.*

Ecological Risk Assessment of Manufactured Nanomaterials

One of the unusual aspects of the field of nanotechnology is the way in which the science of the risk of these materials to the environment has been instigated relatively early in the adoption of the technology. For most other contaminants, the risk assessment has largely been retrospective often decades after the chemical has been in the marketplace and is now distributed across the globe into many environmental compartments. The goal of this science to date has been to determine how a particulate form of a chemical in a nanosize range influences its toxicity versus its larger bulk counterparts. A further goal is to determine how small changes in surface chemistries, size, shape, and structure affect the interaction with organisms in the environment with the goal of informing industry on safe development. However, there are issues in assessing the risk of nanomaterials that are unique to this class of potential contaminant, and therefore the process of assessing risk also has unique considerations (some that have been mentioned in dealing with human health considerations). The assessment of ecological risk is also more complicated than human health assessments, as there are more species involved and higher level impacts on populations, communities of organisms, and ecosystem function need to be considered. The methods to evaluate the potential impacts of nanomaterials at higher levels of organization (community, ecosystem) have not been developed as is the case with many other chemicals.

The basic framework used for ecological risk assessment (Fig. 29-25) (EPA EPA/630/R-95/002F) involves problem formulation, analysis, and risk characterization. Problem formulation involves selecting endpoints of concern and developing a plan for determining impacts on important endpoints (such as a species decline and ecosystem changes). Analysis involves evaluating the potential for exposure to stressors and potential effects at those exposure levels. Risk characterization involves taking the information on important endpoints and the analysis of exposure and effects data to determine the importance of a stressor. For nanomaterials, most of the ecological risk assessment research has been conducted as the analysis of effects of a limited number of commercially available materials, using traditional acute single-organism mortality endpoints of a few select species and with little information regarding sublethal types of effects or other endpoints of concern at the community or ecosystem level. In addition, the concentrations of exposures are much higher than what is considered to be a probable environmental level. As such it is difficult to draw conclusions of the actual risk of many of even the most common materials and the conclusion is often that these particles may not cause any impact as no acute toxicity is seen. Nanomaterials may also be transformed within the environment, and therefore the toxicity of the initial nanomaterial may not provide a complete idea of the toxicity over the lifetime of the material (Nowack et al., 2012). Part of this is due to the relative newness of this field, the particulate nature of the potential toxicants, and other challenges surrounding the methods for determining toxicity, methods for measuring potential exposures, and uncertainty in estimates of how the materials will be used in the future marketplace. Agencies involved in protecting public and environmental health in individual countries as well as international agencies are grappling with methods to develop a structure to assess risk for all nanomaterials and make predictions regarding new ones as they come into the marketplace. This assessment may take time as methods' development needs to progress with the field



Nanoparticle type	Hydrodynamic diameter
nC60	637.7 nm
C60-OH	171.1 nm
C60-BCD	103.7 nm
SWCNT-low func	1.4 nm in one dimension, μM in total

Figure 29-25. *Example of the differences in larger particle agglomerates with nanomaterial.* All three of these are fullerene particle; however, the unfunctionalized particles are two to six times larger agglomerates in a pure water suspension compared with the functionalized counterparts. The stability in suspension also differs with functionalization (represented by the zeta potential).

of nanotechnology as new materials are being developed. The current state of the field is represented below, but the reader should keep in mind that it is rapidly changing.

Toxicity of Manufactured Nanomaterials

Complications of Assays Traditionally, ecotoxicology assays follow standard protocols and involve a group of species that has been selected to be representative of various organisms in the environment, including Daphnia, bacteria, fish, birds, and insects. The most standard assays involve 24- to 48-hour exposures and mortality endpoints such as LD50. Other standard assays for these species include month-long trials assessing growth and reproduction, tumor development, and other endpoints. Some issues arise in conducting these assays for nanomaterials, which is one of the reasons the current toxicological information regarding nanomaterials is variable. Some of the major issues in toxicology assays include delivery of nanomaterials in media and approximating environmental conditions, characterizing exposures, maintaining exposures throughout an assay, and determining the state of exposure throughout an assay. For example, many nanomaterials are not easily dispersible and aggregate substantially when introduced into common exposure media. A hydrophobic particle will aggregate with other particles in water and to an even greater extent when salts are introduced into the media as is the case with many aquatic systems. This causes several issues when determining toxicity. First, the nanomaterial aggregate may no longer be in the nanosize range (hydrodynamic diameter >100 nm). In some cases, this larger aggregate is nevertheless more toxic than its bulk chemical counterpart. This has not been shown with all nanomaterials, however, and is controversial. Second, the nanomaterials as they aggregate settle out of suspension, so depending on the organism involved the actual exposure may change over time as particles are effectively removed from suspension, or they may increase as some organisms (Daphnia) collect particles not only from the water column but from the bottom of the vessel. Some researchers have attempted to suspend the nanomaterials using solvents or detergents for better distribution. Studies have shown that the solvent or detergent when not removed from the nanomaterials sufficiently can cause toxicity (Lovern and Klaper, 2006; Henry et al., 2007; Kovochich et al., 2009), and in others the data indicate that this smaller aggregate size created by the additive changes the toxicity (e.g., Lovern and Klaper, 2006). Researchers have attempted to circumvent this issue by either changing the surface chemistry of the nanomaterial to make it more readily suspendable by adding a hydrophilic functional group or by altering the exposure conditions to include organic material that assists in suspension. Each of these approaches raises its own issues for toxicology. Changing the surface chemistry of a nanomaterial can also change its toxicity (Klaper et al., 2010). The relationship between surface chemistry and toxicity is important to understand because surface functionalization is an important aspect of nanomaterial formulation for industrial applications. So determining the impact of different surface chemistry changes is a necessary part of not only ecotoxicology but nanotoxicology in general. A bigger issue is that many coatings can cause toxicity on their own regardless of whether it is attached to the nanomaterial, and has also shown to be removed in certain cases by the organisms in the test media, or the environment the organism inhabits, which dramatically changes the properties of the nanomaterial through the experiment (Roberts et al., 2007). Is the toxicity then due to the original particle or now to the altered form of the nanomaterial?

As part of determining the dose an organism actually encounters is determining how much of any nanomaterial actually reaches the organism and is taken up into the organism and its tissues. There are several difficulties in quantifying uptake, including identifying the nanomaterial within the matrix of the organism versus inside the organism, for some nanomaterials the issue is distinguishing the nanomaterial from the matrix of the organism or environment either due to their small size relative to other aggregates in a sample, or because of the chemical similarity of the nanomaterial with the matrix (carbon-based nanomaterials in tissue, for example). Bulk extractions of these materials have provided some indication of potential concentrations (Westerhoff et al., 2011), but missing is the finer detail regarding location and structure of nanomaterials within a matrix, which is necessary to determine that the nanomaterial itself is causing an effect and not its byproduct or a secondary physiological response. Another issue in conducting a normal ecotoxicological assay using nanomaterials is the issue of calculating the dose as a mass versus surface area as reported above. Most nanomaterials when reaching the environment are not in a spherical uniform form, which complicates any calculations of dose based on surface area.

The real adverse impacts of nanomaterials may not be due to ambient environmental concentrations that arise but may be due to some subset of materials that are persistent and biomagnify in the environment. Research indicates that various nanomaterials are taken up by organisms in the environment and much is excreted by the organism within hours (Lovern et al., 2008; Petersen et al., 2009). In addition, gold nanomaterials and cadmium selenide quantum dots have been shown to accumulate in tissues of organisms and are able to pass from one level to another in simple food chain experiments (Judy et al., 2011; Werlin et al., 2011). These include microbial food chains and those involving consumption of algae or bacteria into protozoa, herbivores, or detritivores. However, nanomaterials passing from one level to the next do not guarantee biomagnification up the entire food chain as seen in quantum dot studies using transfers from Daphnia to zebrafish or where protozoa take up quantum dots and accumulate them to a greater extent than the media concentration but rotifers feeding on the protozoa do not show further increases in concentrations of nanomaterials (Holbrook et al., 2008; Lewinski et al., 2011).

Ecotoxicity of Nanomaterials

The studies on the toxicity of ENMs to date have largely focused on simple structures of fullerenes, CNTs, metal oxides, and gold and silver particles with a few examples of the impacts of nanomaterials with varying surface chemistries or functional groups. The major conclusion from these data is that toxicity varies with the type of nanomaterial and is not universal across materials. There are varying degrees of toxicity depending on the type of nanomaterial, organism studied, and the co-occurrence of other environmental factors such as UV light, organic carbon, or low pH. The most common endpoints monitored in nanoecotoxicology are acute mortality measures with traditional toxicological models species such as Daphnia, zebrafish, trout, and Arabidopsis. Most studies find some degree of toxicity, but the concentrations of most nanomaterials that are needed to kill half of the sample population are in the mg/L range, which is far above the estimates of potential exposures to any nanomaterial. Nanomaterials may enter other organisms just as they do humans and other mammals, through external contact with outer tissues and breathing structures (gill, skin), and through ingestion. Nanomaterials have been shown to be ingested with and without food present in many circumstances, thus leading to contact with internal structures. The greatest damage measured has been to gill structures in fish and in digestive tissues in other species (Zhu et al., 2008; Bilberg et al., 2010). In terrestrial studies,

plants have been shown to accumulate nanomaterials in root tissues and it is assumed that inhalation is possible in certain terrestrial situations but impacts on birds and mammals other than rats have not been demonstrated.

Fullerenes and CNTs were some of the first nanomaterials investigated for their potential environmental impact. Fullerenes have been shown to be lethal to Daphnia and microbial organisms (e.g., Lovern and Klaper, 2006; Zhu et al., 2006). However, ecotoxicity studies have indicated that the damaging impacts of these nanomaterials can be dramatically impacted by the method of introduction into exposure media. This includes introduction by solvent carriers or by altering the materials with surface chemistries that make them more water soluble. Unmodified fullerene nanomaterials may only be toxic at very high doses of mg/L and mg/kg of soil (Zhu et al., 2006; Li and Alvarez, 2011; Mouchet et al., 2011) and have been shown to have little impact on bacterial communities and protozoa (Johansen et al., 2008). However, increasing their solubility through either solvent or detergent introduction or by changing surface chemistry can also increase their toxicity to aquatic species (Klaper et al., 2010).

Silver nanomaterials are some of the most widely used materials and appear to demonstrate the greatest toxicity of materials investigated in the literature. Silver, in particular, is toxic at μg/L doses to a variety of organisms (George et al., 2011; Bilberg et al., 2012). However, silver and other metal nanomaterials are subject to dissolution even with various coatings and their entire toxicity may be due to the ionic component of an exposure rather than the nanomaterial form (Kennedy et al., 2010). These metal ions may accumulate in the body of organisms after ingestion of nanomaterials and contribute to toxicity (Asharani et al., 2008; Li et al., 2011). Rather than creating a free radical in media, the impacts of metal nanomaterials may be due to metal imbalance in cells after uptake and accumulation, leading to apoptosis and cellular disregulation (Kao et al., 2012). However, it has been suggested that the dissolution and ionic form of the metals is not the sole reason for nanometal toxicities (Griffitt et al., 2007). Nanosilver and possibly other nanomaterials based on soft metals may also react with environmental sulfides to produce silver sulfide nanomaterials, in which the silver bioavailability and toxicity is much reduced (Kim et al., 2010; Liu and Hurt, 2010).

Mechanisms of Toxicity

As in mammalian toxicology studies, oxidative stress has been implicated as a major way in which nanomaterials exert toxicity either by generating free radicals within the suspension media or by changing the chemistry of the cells in which they come in contact. Metal oxide nanomaterials, in particular, have been found to generate oxidative stress. Hydroxyl radicals and oxidative stress have been found to increase over time in the presence of metal oxides and UV light (Yu et al., 2011). As in human tissues, the stimulation of oxidative stress pathways alone is not an indication of harm and may be countered by adaptation by the organism to exposure. Mortimer et al. (2010) found that despite oxidative stress in initial assays, toxicity decreased over time in protozoa after exposure to metal oxide nanomaterials. However, Klaper et al. (2009) found that acute assays of oxidative stress do provide an early indicator of mortality of Daphnia in chronic assays for a variety of nanomaterial types. Metal oxide nanomaterials appear to have greater toxicity than their bulk counterparts. Titanium dioxide nanomaterials generate more ROS per gram than similar macroparticulates (Xiong et al., 2011). However, they do not differ from larger aggregates in their toxicity to developing fish (Zhu et al., 2008). Most studies have found a greater difference among nanomaterials composed of different metal oxides than the difference between the bulk and nanomaterial form of these compounds.

Metal nanomaterials have been found to cause a suite of effects, which in fish include negative impacts on respiration, oxidative stress, and development (Zhu et al., 2008; Shaw and Handy, 2011), in *Caenorhabditis elegans* increased mortality and decreased reproduction (Wang et al., 2012) and inhibit algal growth (Peng et al., 2011). Differences among metal oxides may be a result of differential solubilities in media.

The toxicity of nanomaterials to aquatic organisms can be greatly dependent upon the interaction of nanomaterials with the media to which they are introduced (Figs. 29-26 to 29-28). For example, dissolution of metal oxides and metal nanomaterials is greatly impacted by the characteristics of the media such as pH and salt content. Li et al. (2011) found that zinc oxide nanomaterials were most toxic in ultrapure water followed by salt, lithium borate (LB), and phosphate buffer saline (PBS) buffers. In the environment, toxicity may differ with the presence of organic matter, and the specific interaction of organic matter with a nanomaterial will differ depending on its composition. The degree of interaction of nanomaterial and organic matter has been shown to impact toxicity (Gao et al., 2009). Toxicity of particles sorbed to natural organic matter can be significantly greater (Edgington et al., 2010) or diminished (Blinova et al., 2010). Toxicity of nanomaterials can be significantly impacted by the surface chemistry, capping agents, and coatings of the particles. Additions of functional groups have been shown to increase toxicity in some cases (Klaper et al., 2009, 2010) and decrease toxicity in others (Allen et al., 2009). A few studies have also examined the influence of aging of nanomaterials in the environment on their toxicity.

Nanomaterials may also impact the bioavailability and toxicity of other contaminants in the environment. Fullerene and CNT particles, in particular, have been shown to bind to various organic contaminants with the strength of the association dependent upon

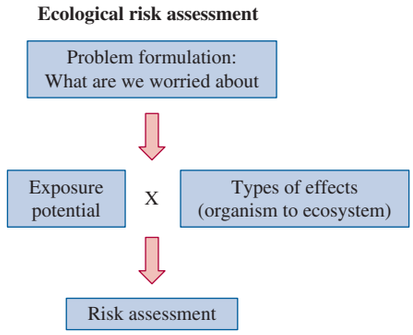


Figure 29-26. *Ecological risk assessment involves determining the types of concerns we have regarding a particular stressor and its impacts, determining the potential for exposure to environmental compartments, the types of potential impacts a stressor (in this case a nanomaterial) may have at those exposures, and using those two factors together to determine the risk to the environment.* With most nanomaterials we are relatively certain that environments such as freshwater systems that are receivers of wastewater will be exposed and most likely agricultural areas that receive solid wastes. The level of exposure is still in question and we have only begun to examine the types of effects. We have some information on model species such as Daphnia and trout as to the chance of mortality and some physiological effects in the acute exposure but little information is available on chronic low-level exposures. As such, it is currently premature to determine the actual risk to the environment.

Figure 29-27. *Suspension characteristics can have a significant impact on toxicity.* In this case single-walled nanotubes that have been functionalized with polyethylene glycol remain in suspension (on right) where their unfunctionalized counterparts do not (on left).

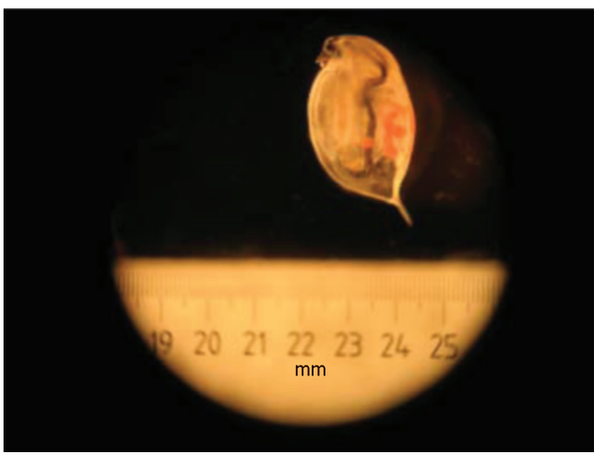

Figure 29-28. *Aquatic organisms, such as Daphnia magna, readily take up nanomaterials from the environment and their guts are rapidly filled with nanomaterials.* Some of these materials have been found to cross the gut barrier and translocate into other tissues within the organism.

the compound. Sorption to these nanomaterials can increase concentrations of bound organics by up to 60%, which if ingested could increase their toxicity (Baun et al., 2008).

As many nanomaterial exposures in the environment will occur at relatively low levels (μg to ng/L exposures), it is important to use assays other than LD50 to indicate the most relevant environmental effect. Including sublethal assays of physiology, assays of impacts of chronic low-level exposures, monitoring of alternative endpoints such as reproduction, growth, and at a higher level changes in community structure and ecosystem function, are essential. Nanomaterials cause a shift in overall behavior in Daphnia, which can indicate a greater susceptibility to predators and a greater energy cost leading to decreased reproduction (Lovern et al., 2007; Brausch et al., 2011). Various nanomaterials have been shown to impact development and physiology of fish species causing greater apoptosis in tissues, stress, and other impacts including structural effects (Chen et al., 2011; Shaw and Handy, 2011; Xiong et al., 2011; Truong et al., 2012). As the immune response is the first interaction of foreign substances with an organism, it has been shown that nanomaterials are stimulatory to the immune system of fish in particular and have an effect that is equal to the response to bacterial cell components, which may indicate an eventual cost to the organism (Klaper et al., 2010; Jovanović et al., 2011). Nanomaterials also have the potential to be mutagenic and in flies cause mutations that alter the phenotype significantly into the second generation (Vecchio et al., 2012).

Measurements of impacts at the community and ecosystem level are uncommon for nanomaterials, as they are for chemical toxicants with a much longer toxicology history. The existing studies indicate that community structure is impacted by the same nanomaterials that show toxicity and developmental impacts such as metals and metal oxides. Cerium dioxide and silver nanomaterials have a significant impact on marine microbial communities and microbial communities in wastewater—decrease in degradation potential and productivity (Fabrega et al., 2011; García et al., 2012). They also cause shifts in decomposition communities in freshwater streams (Pradhan et al., 2011). Nanomaterials such as unfunctionalized fullerenes that have been shown to be less toxic exhibit no impact on soil community structure (Tong et al., 2007), macrophyte structure (Velzeboer et al., 2011), or mutagenesis across generations (Nyberg et al., 2008) but do cause shifts in community composition of soil bacteria (Johansen et al., 2008). The overall composition may also be altered as microbial communities on mucus secretions of carp are different in those that have been exposed to fullerenes (Letts et al., 2011). The overall community impact is greatly affected by complexity in environmental samples (Kang et al., 2009).

Ecosystem impacts may be impacted by these community effects as bacterial community function has a great impact on nutrient cycling. CNTs have been shown to impact microbial activity (Chung et al., 2011), and fullerenes, silver, and CdSe quantum dots impact sediment bacterial oxidation of organics (Gao et al., 2009).

INTRODUCTION

Ecotoxicology is the science of contaminants in the biosphere and their effects on constituents of the biosphere (Newman, 2015). It follows from this definition that ecotoxicologists examine large-scale ecological phenomenon (Preston, 2002) in addition to those normally addressed in toxicology: ecotoxicology has an overarching goal of explaining and predicting effect or exposure phenomena at several levels of biological organization (Fig. 30-1). Essential explanations and models include those applied in conventional toxicology and a range of environmental sciences.

Although Truhaut's original definition of this new science encompassed effects to humans (Truhaut, 1977), most recent definitions of ecotoxicology do not. Relevant effects to nonhuman targets range from biomolecular to global. Taking on the classic toxicology vantage initially, suborganismal and organismal effects were emphasized during ecotoxicology's nascent stage; however, studies of higher level effects and interactions are becoming increasingly commonplace as the science matures. Such indirect effects[1] were initially considered problematic and reluctantly relegated to secondary importance (Fleeger et al., 2003) relative to direct effects to individuals. Indirect effects are now known to be as or more important as direct effects to nonhuman targets (Fleeger et al., 2003; Chapman, 2004). As the need to predict major effects to populations, communities, ecosystems, and other higher level entities has become increasingly apparent, more cause–effect models relevant to these higher levels of biological organization are added to the conventional set of toxicology models applied by pioneering ecotoxicologists.

Contaminant chemical form, phase association, and movement among components of the biosphere are also central issues in ecotoxicology because they determine exposure, bioavailability, and realized dose. The context of these biogeochemical studies has expanded in the last several decades to encompass issues of larger scale such as global movement and fractionation of persistent organic pollutants (POPs) (Wania and Mackay, 1996).

From a practical vantage, ecotoxicology informs decision makers about ecological risks associated with contamination. Risk to ecological entities is estimated or predicted by combining exposure and effect information. Risk might involve diminished fitness of individuals, increased risk of local population extinction, a drop in species diversity, or reduced nutrient cycling or primary productivity. Because potential ecological endpoints are so diverse, the ecological risk framework tends to be more flexible than that of the conventional human health risk assessment (Fig. 30-2). This important role of ecotoxicology in ecological risk assessment (ERA) is discussed in more detail in this chapter.

SOME DISTINCT ASPECTS OF EXPOSURE

Predicting exposure and effect is difficult for all relevant ecological entities. In contrast to human toxicology in which information about a few species might be used to predict harm to one (humans), ecotoxicology commonly uses sparse information for a few species to predict effects to many species and their interactions. Identifying exposure pathways, bioavailability, bioaccumulation, and toxicant transfer for all at-risk ecological receptors requires considerable effort.

[1]Indirect effects are effects of toxicants mediated by another ecosystem component (Krivtsov, 2004), such as those that might occur to a flowering plant if a pesticide were to eliminate its primary insect pollinator.

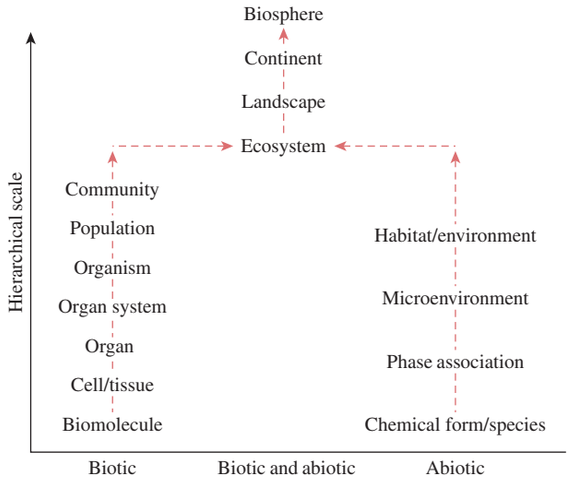

Figure 30-1. *Ecological scales relevant to ecotoxicology.* Solely biological scales relevant to ecotoxicology range from the molecular to the community levels: solely abiotic scales range from the chemical to the entire habitat. Biotic and abiotic components are usually combined at levels above the ecological community and habitat. The ecological community and physicochemical habitat combined to form the ecosystem. Ecological systems can be considered at the landscape scale, such as the combination of marine, freshwater, and terrestrial systems at a river's mouth. Recently, the continental and biospheric scales have become relevant as in the cases of ozone depletion, acid precipitation, and global warming.

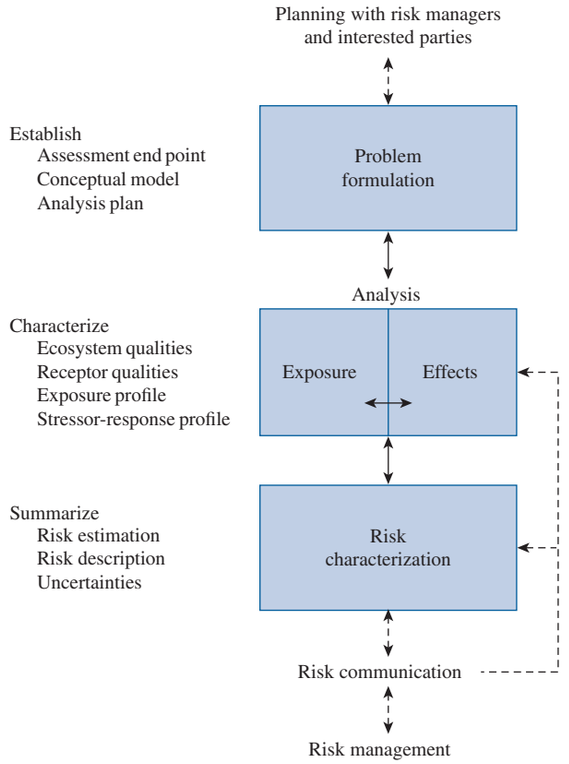

Figure 30-2. *The general form of an ecological risk assessment including problem formulation, analysis, and risk characterization stages.* Problem formulation is done in dialog with risk managers and stakeholders, and involves a clear statement of the ecological entity to be assessed, a conceptual model for the process, and a plan for conducting the assessment. The analysis stage involves exposure and effects characterizations. Using the context developed during problem formulation and information organized together in the analysis stage, a statement of risk and associated uncertainties are made in the risk characterization stage.

Relevant exposure routes are the conventional ingestion, inhalation, and dermal absorption. But unique features of exposure pathways must be accommodated for species that ingest a wide range of materials using distinct feeding mechanisms, breathe gaseous or liquid media using extremely different structures, and come into dermal contact with a variety of gaseous, liquid, and solid media.

Prediction of oral exposure can be compromised because species feed on different materials; however, conventional principles regarding oral bioavailability remain relevant. As an example, some birds are uniquely at high risk of lead poisoning because they ingest and then use lead shot as grit. Shot are ground together in their gizzards under acidic conditions, releasing significant amounts of dissolved lead (Kendall et al., 1996). As true with humans (i.e., the ionic hypothesis of Mathews [1904]), the dissolved form of lead is more available to do harm than solid lead shot. Similar high risk of lead poisoning is present for some raptors feeding on game birds whose tissues can contain lead shot (Wayland and Bollinger, 1999). As another example, complex sorting of filtered materials on the gills of bivalve molluscs strongly influences the metal content and bioavailability of the material that eventually passes into their guts (Allison et al., 1998). Some invertebrate species have elaborate feeding structures that are also involved in respiration (e.g., lugworms and bivalve molluscs) or locomotion (copepods and other zooplankton species). Some zooplankton species feed and digest algal cells in such a way that only metals soluble in the algal cytosol are readily bioavailable (Reinfelder and Fisher, 1991). Unlike most mammalian species, many invertebrate species are capable of sequestering large amounts of metals in intracellular granules (Mason and Nott, 1981). Incorporation of metals into granules by prey species reduces metal bioavailability to predators (Nott and Nicolaidou, 1993). Just as noted with 5-fluoruracil administration or chronic ethanol consumption, some pollutant exposures cause malabsorption by damaging the intestine wall. A relevant situation is intestinal damage to otters caused by ingestion during grooming of oiled fur (Lipscomb et al., 1996; Ormseth and Ben-David, 2000). The principles remain the same in all of these cases but critical exposure pathway details are different.

Many techniques applied to determining human oral bioavailability are available to the ecotoxicologist; however, as just illustrated, modifications are needed for the many pathways for nonhuman species exposure. Typical are those associated with estimating contaminant bioavailability in aquatic environments. As an example, biomimetic and related extraction methods used to predict human oral bioavailability can be modified to predict sediment-bound contaminant bioavailabilities. Sediments are placed into contact with biomimetic solutions (Chen and Mayer, 1998; Leslie et al., 2002) or digestive fluids taken from organisms (Mayer et al., 1996; Weston and Maruya, 2002), and the amount of extracted contaminant used to estimate bioavailability.

Estimation of chemical speciation is central to predicting bioavailability of water-associated contaminants. Speciation can determine the bioavailability of dissolved metals. Movements of nonionic and ionizable organic compounds across the gut or gills are strongly influenced by lipid solubility and the pH-partition theory, respectively. Consequently, determination of a compound's lipophilicity or calculation of pH- and pK_a-dependent ionization facilitates some predictive capability for bioavailability (see Chap. 5, "Absorption, Distribution, and Excretion of Toxicants"). A common application of this approach would be estimation of water pH effects on

ammonia toxicity as the consequence of the ease with which unionized ammonia passes through gills relative to ionized ammonia (Lloyd and Herbert, 1960). The free ion activity model (FIAM) and biotic ligand model (BLM) state that uptake and toxicity of cationic trace metals are best predicted from the interaction of the free ion with ligands on biological surface (Campbell and Tessier, 1996; Erickson, 2013), although exceptions exist to this extension of the ionic hypothesis. Consequently, dissolved metal exposure assessments often begin by estimating the amount of a metal present as the free ion. Normally, such calculations require only thermodynamic modeling based on measured concentrations of dissolved cations and anions. Lipid partitioning is often used to predict dissolved, nonionizing organic compound accumulation in and effects to aquatic biota. The propensity for an organic compound to accumulate in aquatic organisms increases with lipid solubility as often described with a simple quantitative structure–activity relationship (QSAR) (Neely et al., 1974; Mackay, 1982; Chiou, 1985; Connell, 1990). The log of the octanol–water partition coefficient (log K_{ow}) is used to predict measures such as the bioconcentration factor (BCF; the quotient of the concentration in the organism and that in the water from which the organic compound is being accumulated):

$$\mathrm{BCF} = \frac{C_{\mathrm{Organism}}}{C_{\mathrm{Water}}}.$$

Bioavailability, bioaccumulation, or exposure concentrations for sediment-associated toxicants are also approached by considering chemical speciation and phase partitioning. Metals in sediments are either incorporated into one of many solid phases or dissolved in the interstitial waters surrounding the sediment particles. Bioavailabilities of metals in these different forms are difficult to predict (Luoma, 1989) but, nonetheless, various schemes have been applied to that end. Bioavailable metals have been estimated by normalizing sediment metal concentrations to easily extracted iron and manganese concentrations because solid iron and manganese oxides sequester metals in poorly bioavailable solid forms (Luoma and Bryan, 1978). Other chemical extraction methods have been applied with some success (Tessier et al., 1984). A pragmatic method for predicting sediment metal bioavailability has emerged that is based on the assumption that the sediment metal form of most concern is the dissolved metal. Further, for many metals and sediments, the dissolved interstitial metal concentrations are determined by equilibrium between solid (iron and manganese) sulfides and the interstitial water:

$$\mathrm{Cd}^{2+} + \mathrm{FeS}_{\mathrm{Solid}} \leftrightarrow \mathrm{CdS}_{\mathrm{Solid}} + \mathrm{Fe}^{2+}.$$

Because the equilibrium so favors formation of metal sulfide ($\mathrm{CdS}_{\mathrm{Solid}}$ in this case) at the expense of $\mathrm{FeS}_{\mathrm{Solid}}$, insignificant amounts of dissolved metal will be present in the interstitial waters if enough $\mathrm{FeS}_{\mathrm{Solid}}$ is present. This premise has given rise to a standard technique for determining whether sediments might contain enough metal to warrant concern (Di Toro et al., 1990). First, a sediment aliquot is extracted with cold hydrochloric acid. Then the amounts of sulfide (acid volatile sulfides [AVS]) and simultaneously extracted metals (SEM) are quantified in that extract. The difference between the SEM and AVS suggests whether or not enough metal will remain dissolved in the interstitial waters to warrant concern. This method has enjoyed wide application and was subsequently refined by Di Toro et al. (2005) by including metal partitioning to sediment organic matter. Further refinement remains to be done because metal exposure of organisms that ingest sediment particulates is not fully defined by interstitial water concentrations alone (Lee et al., 2000).

Bioavailability and accumulation of sediment-associated organic compounds are predicted with tools similar to those described for waters. The bioavailability of ionizable organic compounds can be approximated with the pH-partition hypothesis that relates the availability of an ionizable compound to the diffusion of its unionized form through membranes as determined by pH and pK_a. Availability of nonionizing organic compounds for accumulation can often be estimated with its log K_{ow} and equilibrium partitioning theory as described already for accumulation from waters. The challenge with nonionizing organic compounds becomes adequately defining the phases between which the compound is partitioning. This might be done by estimating the partitioning of the compound between sediment solid phases and the interstitial water as done by Di Toro et al. (1991). Descriptions of nonionizing organic compound bioaccumulation from sediments can also entail normalization of concentrations to phases thought to be dictating partitioning:

$$\text{Biota sediment accumulation factor (BSAF)} = \frac{\mu\text{g/kg lipid}}{\mu\text{g/kg organic carbon}},$$

where the mass of compound in the organisms is divided by kilograms of organism-associated lipid and the mass of compound in the sediment is divided by kilograms of sediment-associated organic carbon.

Another issue of importance to the ecotoxicologist is the possibility of biomagnification, the increase in contaminant concentration as it moves through a food web. Biomagnification occurs for many persistent organic pollutants (POPs) and some organometals such as methylmercury. MacDonald et al. (2002) conceptualize biomagnification as environmental amplification involving sequential steps of solvent switching followed by solvent depletion. Solvent switching might involve partitioning of the compound from water into the lipids in prey tissues. Next, after the predator ingests a prey, digestion of the prey lipids leads to POP partitioning into lipids of the predator tissues. The result of solvent switching and then depletion is a net increase in POP concentration in the predator relative to the prey. As will be described in the Section "Community," biomagnification can result in harmful exposures to species situated high in the food web such as birds of prey.

TOXICANT EFFECTS

While determining *exposure* comprises one half of the risk assessment paradigm, the other half, understanding chemical effects, lies at the heart of toxicology and, hence, comprises the focus of this chapter. The effects, or deleterious consequences of chemical exposures, can be enormously diverse as demonstrated by previous chapters, and investigated by numerous techniques. One approach to this complex topic of ecotoxicological effects, which we employ here, is to organize effects according to biological levels of organization. Thus, one may consider effects, in ascending order, at the subcellular (molecular and biochemical), cellular, organismal, population, community, ecosystem, or higher levels of organization. As noted earlier, an important distinction between traditional biomedical, or human health-oriented, toxicology and ecotoxicology is the emphasis by the latter on higher levels of biological organization, specifically populations, communities, and ecosystems, while biomedical toxicology focuses on lower levels, from organismal and below. This difference arises from the focus of biomedical toxicology on one species and concerns for protecting the health of individuals of that species. Ecotoxicology, in contrast, deals with,

theoretically at least, all species, and in line with other aspects of natural resource management, the primary concern is one of sustainability. That is, policies and regulations surrounding chemical effects in natural ecosystems are designed to protect ecological features such as population dynamics, community structures, and ecosystem functions. In this light, the individual organism is essentially viewed as expendable, as long as these higher level variables are protected. An exception here is that of endangered or threatened species, where the loss of an individual may have unacceptable legal or ecological consequences.

While higher levels of organization comprise the ultimate focus of those concerned with chemical pollution of natural systems, the science of ecotoxicology includes studies across the entire hierarchy. Studies at lower levels (cellular and below) provide insights into mechanisms of toxicity that can be valuable for making predictions among related compounds or species, and establishing cause–effect relationships in field studies, for generating useful "biomarkers" of chemical exposure and effect, and for providing insights into higher level, often population level, effects. Studies at the organism level have historically played a dominant role in regulatory ecotoxicology; many traditional bioassays, described later, can be viewed as organismal-level queries. Again, understanding effects at the population and higher levels can be viewed as the ultimate goal of ecotoxicology. However, because these effects can require a relatively long time beyond the initial exposure of a system to emerge, their quantification is often difficult, and they generally do not serve to identify the nature of the stressor. Thus, the elucidation of effects of chemical pollutants, as well as other stressors, in natural systems draws on multiple approaches and conclusions are generally based on the weight of evidence available. Adams (2000) discusses examples of effects, or endpoints, that can be measured spanning levels of organization including their relative sensitivities and ecological relevancies, and the importance of integrating studies across levels of organization and mathematical approaches for accomplishing.

An important paradigm that has emerged recently for elucidating linkages across levels of organization is the "Adverse Outcome Pathway" (AOP) concept first described by Ankley et al. (2000). They define the AOP as "a conceptual construct that portrays existing knowledge concerning the linkage between a direct molecular initiating effect (e.g., a molecular interaction between a xenobiotic and a specific biomolecule) and an adverse outcome at a biological level of organization relevant to risk assessment." A generalized AOP is presented in Fig. 30-3. In the realm of ecotoxicology and ecological risk assessment, the population is the level generally of greatest relevance. Subsequent papers have addressed the development of the AOP concept, for example, in terms of underlying principles (Villeneuve et al., 2014a), best practices for international harmonization of approaches and databases (Villeneuve et al., 2014b), and the integration of computational and modeling approaches (Perkins et al., 2015). The AOP concept provides perhaps an unusual example of an approach originally developed by ecotoxicologists that has been adopted by the biomedical field (e.g., see Edwards et al., 2016).

In the following sections, we describe important chemical effects that have been addressed at different levels of biological organization in ecotoxicological contexts, including illustrative examples. It is beyond the scope of this chapter to provide discussions of all chemicals that have received ecotoxicological attention. Other chapters in this text, particularly those in Unit V, provide detailed information for most classes of chemicals of concern as pollutants of natural systems, albeit in a primarily mammalian context. Many of the effects described are relevant to other animals, and of course mammals do occur in natural systems! Some plant-specific effects will be addressed herein. It should be noted that, while we have employed a biological level of organization approach as a meaningful way to organize and convey a complex array of information, the phenomena we have categorized into various levels are ultimately interwoven, as will become apparent.

Molecular and Biochemical Effects

This lowest level of organization includes fundamental processes associated with the regulation of gene transcription and translation, biotransformation of xenobiotics, and the deleterious biochemical effects of xenobiotics on cellular constituents including proteins, lipids, and DNA. These effects have been described elsewhere throughout this book in various contexts related to human health. Here we will highlight some aspects of subcellular effects that have received particular attention in the context of ecotoxicology.

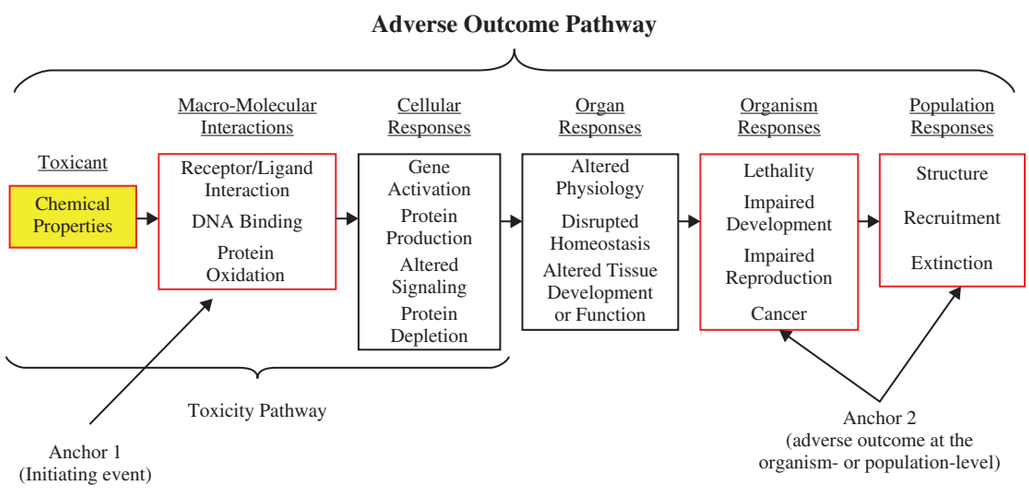

Figure 30-3. *An adverse outcome pathway (AOP) is a conceptual framework that portrays existing knowledge concerning the linkage between a direct molecular initiating event and an adverse outcome at a level of biological organization relevant to risk assessment.* (From Ankley et al. [2010]; used with permission from Wiley.)

Research in this area has been performed for a variety of reasons, including the elucidation of mechanisms of adaptation and toxicity, understanding species similarities and differences (e.g., to compare selected wildlife species with standard mammalian models, and to identify particularly sensitive species), and developing useful biomarkers of chemical exposure and toxicity for environmental assessments. More in-depth discussions are provided in monographs such as Hoffman et al. (2003), Newman (2015), Mommsen and Moon (2005), Di Giulio and Hinton (2008), and Walker et al. (2012).

Gene Expression and Ecotoxicogenomics

A long-standing mechanistic issue in toxicology concerns chemical effects on gene and protein expression. Xenobiotics can affect gene transcription through interactions with transcription factors and/or the promoter regions of genes that bind transcription factors in the process of activating transcription. In the context of environmental toxicology, perhaps the most studied xenobiotic effects involve ligand-activated transcription factors. These intracellular receptor proteins recognize and bind specific compounds, thus forming a complex that binds to specific promoter regions of genes, thereby activating transcription of mRNAs, and ultimately translation of the associated protein. Two examples of substantial importance in ecotoxicology that illustrate these interactions involve the estrogen receptor (ER) and the aryl hydrocarbon receptor (AhR).

Estrogen Receptor A number of chemicals have been shown to perturb various components of the endocrine system, and the identification and elucidation of "endocrine disruptors" have been a subject of much research and regulatory action in recent years, in the contexts of both human and wildlife health (see Chap. 10, "Developmental Toxicology," Chap. 20, "Toxic Responses of the Endocrine System," and Chap. 21, "Toxic Responses of the Reproductive System"; Rotchell and Ostrander, 2003). Perhaps the most studied component of the vertebrate endocrine system in this context is the ER, particularly ER-α, and responses associated with it. The dominant natural ligand for this nuclear receptor is estradiol (E2); binding of E2 with ER produces a complex that can then bind to estrogen response elements (ERE) of specific genes that contain one or more EREs, thereby causing gene transcription (see Fig. 30-4). Genes regulated in this manner by E2–ER play various important roles in, for example, sexual organ development, behavior, fertility, and bone integrity (Deroo and Korach, 2006).

A number of chemicals including certain drugs and environmental pollutants can serve as ligands for ER; in most cases these "xenoestrogens" activate gene transcription, that is, similar to E2, acting as receptor agonists. The first xenoestrogen identified was diethylstilbestrol (DES), a drug used to prevent miscarriage in the 1940s to the 1970s until it was discovered to have profound developmental effects in some offspring of women receiving the treatment (Trimble, 2001). Since then, a number of environmental pollutants with estrogenic activity have been identified, including certain chlorinated hydrocarbon insecticides (e.g., DDT, methoxychlor, and endosulfan), surfactants (nonylphenol), some polychlorinated biphenyls (PCBs), bisphenol A (used in plastic manufacturing), and ethinyl estradiol, a synthetic estrogen used in birth control pills and observed in municipal effluents and surface waters (Shelby et al., 1996; Larsson et al., 1999; van der Oost et al., 2003) (see Fig. 30-5).

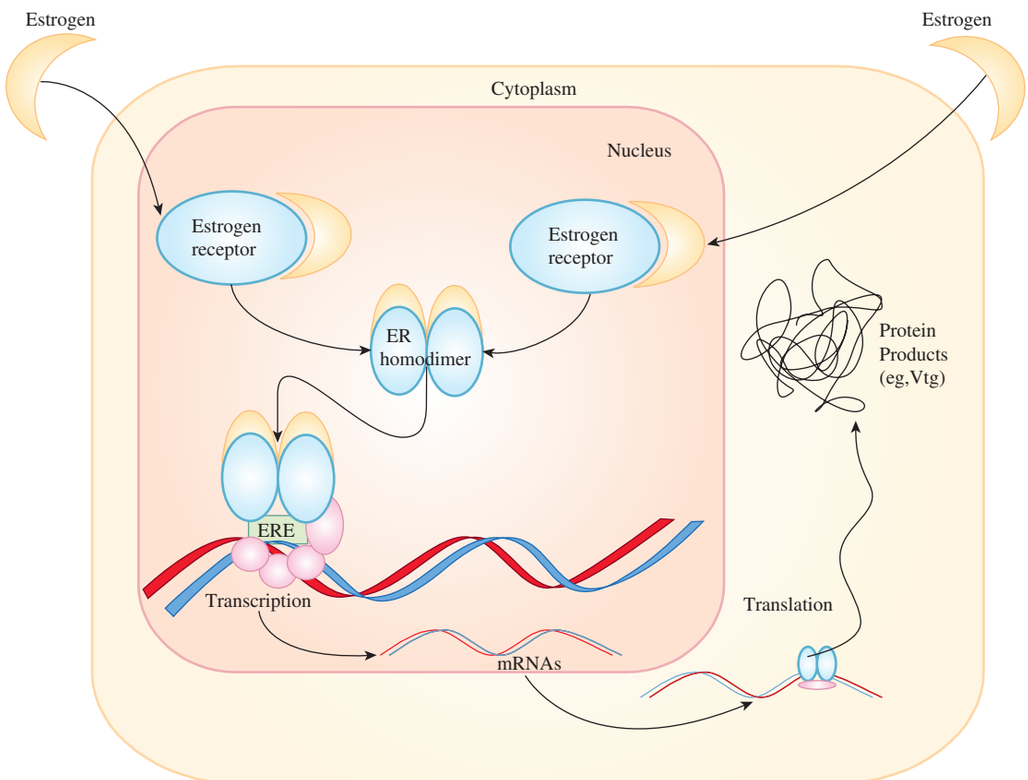

Figure 30-4. *A simplified model of estrogen receptor signaling including the estrogen receptor (ER), which on binding to native hormone ligand (estrogen) or xenoestrogen (see Fig. 30-5) forms the transcriptionally active ER homodimer complex that binds to genes containing estrogen response elements (ERE) and thereby upregulates transcription and translation of genes/proteins regulated by the system, such as vitellogenin (Vtg).* (Figure kindly provided by Carla Rosenfeld, Duke University.)

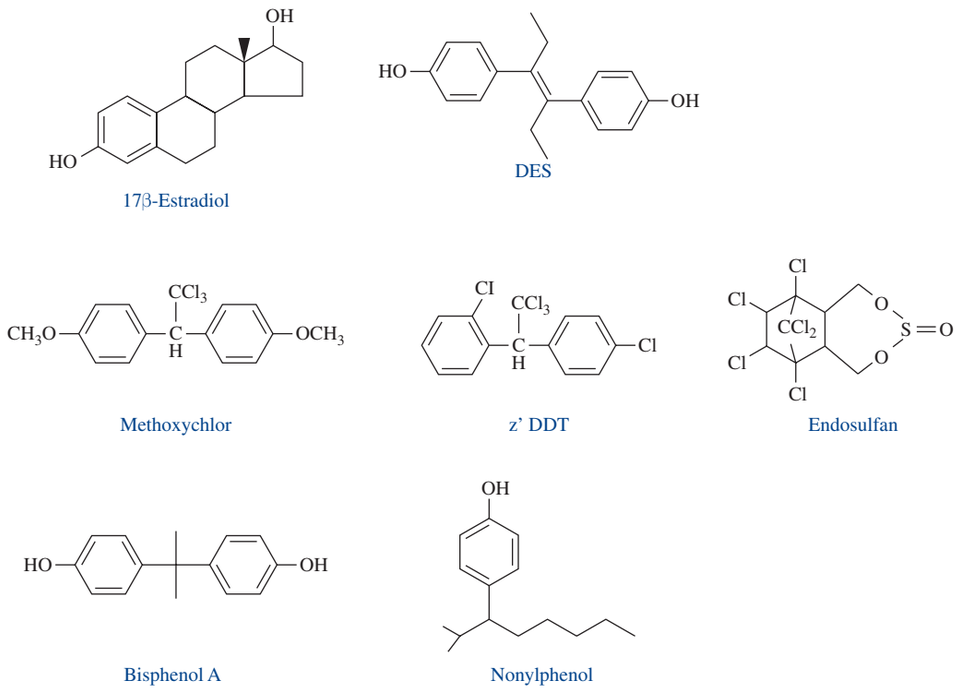

Figure 30-5. *Estrogen receptor agonists, including a native estrogen (17β-estradiol), the drug diethylstilbestrol (DES), a surfactant component (nonylphenol), an industrial intermediate (bisphenol A), and several pesticides (remainder).*

With the exception of ethinyl estradiol, these pollutants exhibit relatively low binding affinities to ER, as compared with E2 or DES (Shelby et al., 1996); however, environmental exposures may be sufficient to perturb reproduction or development.

Evidence for such "endocrine disruptions" by environmental xenoestrogens appears to be overall stronger for wildlife than for humans, likely due to instances of elevated exposures that are less prone to confounding factors than is typically the case for human exposures. Also, egg-laying vertebrates provide a unique biomarker of estrogen exposure that has contributed to ecotoxicological studies in this area. Vitellogenin (Vtg) is a protein that is normally produced by the liver of females and transported via the bloodstream to the ovary where, as a key component of yolk, it provides nourishment to the developing embryo. The production of Vtg is regulated by the estrogen–ER system. Interestingly, males of egg-laying vertebrate species contain the molecular machinery to produce Vtg, but production and circulating levels are normally very low, due to low titers of estrogen. However, exposures of males to estrogen and xenoestrogens upregulate Vtg production, which can be readily measured in blood samples. Consequently, elevated Vtg in males of these species is a useful biomarker of estrogenic chemical exposures (Sumpter and Jobling, 1995; see the section "Biomarkers"). Examples include rainbow trout (*Oncorhynchus mykiss*) caged in surface waters below industrial or municipal effluent sources enriched in alkylphenolic surfactants in the United Kingdom (Harries et al., 1997) or natural and synthetic estrogens in Sweden (Larsson et al., 1999), whitefish (*Coregonus lavaretus*) caged near paper mill effluents in Finland (Mellanen et al., 1999), and in tropical fish inhabiting a wastewater-impacted river in Brazil (Pimentel et al., 2016). While the bulk of research related to estrogenic compounds in natural systems has focused on fish, this approach has merit for other egg-laying vertebrates (Lorenzen et al., 2003; Huang et al., 2005), and for some invertebrates that produce Vtg-like proteins (Porte et al., 2006).

Aryl Hydrocarbon Receptor The AhR is a member of the basic helix–loop–helix Per ARNT Sim (bHLH-PAS) family of receptors/transcription factors that play roles in development, as sensors of the internal and external environment in order to maintain homeostasis, and in establishment and maintenance of circadian clocks (Denison and Nagy, 2003; Hahn et al., 2005). The AhR is among the most intensively studied receptors in toxicology due to its role in regulating a number of genes coding for proteins involved in xenobiotic metabolism, and its responsiveness to a number of widespread environmental contaminants, as well as some drugs and endogenous compounds. The AhR is a ligand-activated cytosolic receptor that on binding to a ligand traverses to the nucleus where it complexes with another transcription factor, the AhR nuclear translocator (ARNT) protein (Fig. 30-6), to form a transcriptionally active dimer. This AhR–ARNT complex binds to promoter sequences of genes regulated by the AHR system; these promoters are most often referred to as "xenobiotic response elements" (XRE) or "dioxin response elements" (DRE).

Characterized genes that are upregulated by the AhR system in large part code for enzymes involved in the metabolism of lipophilic chemicals, including organic xenobiotics and some endogenous substrates such as steroid hormones. These enzymes include specific cytochrome P450s (mammalian CYP1A1, 1A2, and 1B1 and their counterparts in other vertebrates), a glutathione transferase (GST), a glucuronosyl transferase (UDPGT), an alcohol dehydrogenase (ALD), and a quinone oxidoreductase (NQO). In addition to these enzymes, AhR–ARNT upregulates the AhR repressor protein (AhRR), which then competes with AhR for ARNT. This results in a transcriptionally inactive complex and effectively provides a negative feedback loop for controlling AhR-mediated gene transcription (Hahn et al., 2005). The biotransformation enzymes regulated by the AhR system are described in detail in Chap. 6, "Biotransformation of Xenobiotics." Briefly, they play key roles for transforming many lipophilic chemicals, including numerous

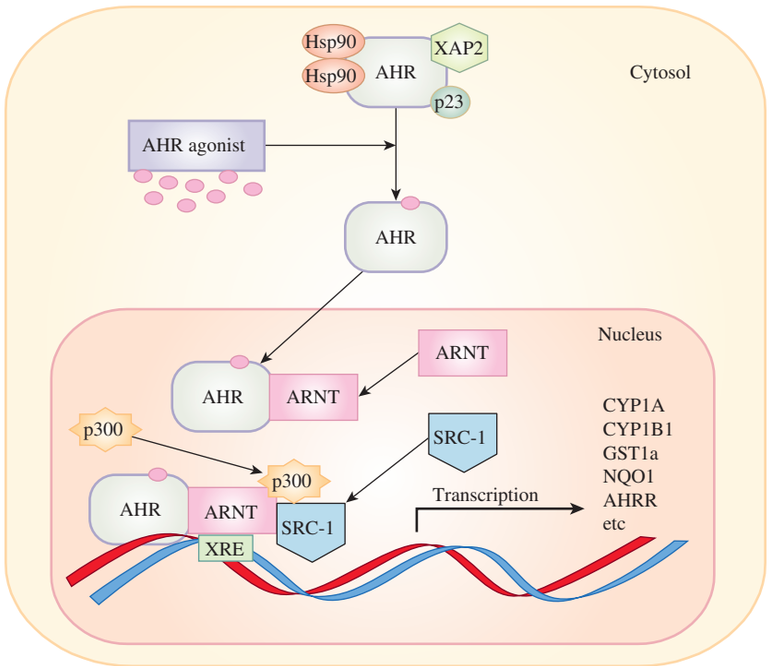

Figure 30-6. *A simplified model of the aryl hydrocarbon receptor (AHR) including activation by AHR ligands (see Fig. 30-7) which allows for dimerization with the AHR nuclear transporter (ARNT) that forms the transcriptionally active complex which binds to xenobiotic response elements (XRE) and thereby upregulates a number of genes, including several involved in biotransformation, indicated here, as well as the AHR repressor (AHRR) that provides negative feedback control of the system.* Hsp90, XAP2, and p23 are chaperone proteins; SRC-1 and p300 are examples of coregulator proteins involved in transcription. (Figure kindly provided by Carrie Fleming and Carla Rosenfeld, Duke University.)

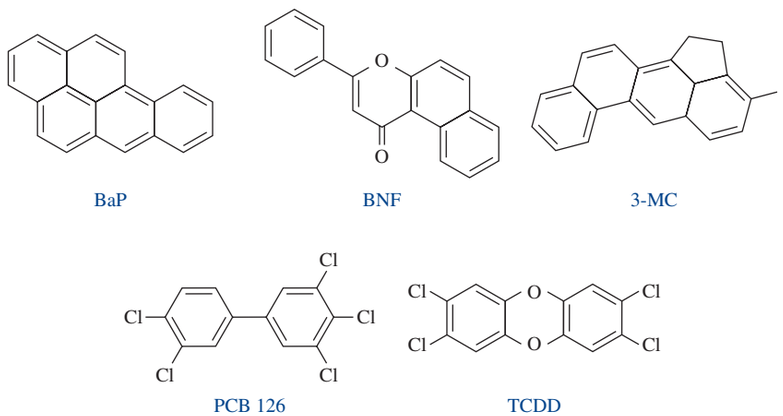

Figure 30-7. *Representative ligands of the aryl hydrocarbon receptor, including 2,3,7,8-tetrachlorodibenzodioxin (TCDD), a coplanar polychlorinated biphenyl (PCB 126), two polycyclic aromatic hydrocarbons (benzo(a)pyrene [BaP] and 3-methylcholanthrene [3-MC]), and a flavone (β-naphthoflavone [BNF]).*

common organic contaminants, into more water-soluble, and hence excretable, products. However, this biotransformation activity can result in production of highly reactive products that are more toxic than their parent compounds, that is, "activation."

Of particular relevance to the present discussion, however, is the ability of some ubiquitous pollutants to act as AhR ligands and markedly upregulate gene transcription via the AhR–ARNT signaling pathway described above (Denison and Nagy, 2003). In some cases, this can be interpreted as an adaptive response—the organism is reacting to exposure to a lipophilic xenobiotic in order to enhance its elimination. However, as noted above, biotransformation can also lead to enhanced toxicity of some substrates. The two major classes of pollutants that have members that act as ligands for the AhR and upregulate gene expression (and thereby "induce" biotransformation enzymes) and have received the greatest attention in ecotoxicology are the polycyclic aromatic hydrocarbons (PAHs) and the polyhalogenated aromatic hydrocarbons (pHAHs); examples of both are provided in Fig. 30-7. The most studied pHAHs are particular "coplanar" PCBs and chlorinated dioxins. While some PAHs and pHAHs share the ability to activate the AhR, important differences between these classes exist. PAHs, whether they are ligands for the AhR or not, are overall very good substrates for the biotransformation systems upregulated via the AhR, which can act to both detoxify and enhance the toxicity of some PAHs (discussed in the section "Cancer" later in this chapter). In general, pHAH-type AhR ligands are more potent AhR ligands and enzyme inducers than

PAHs, but due to extensive halogenation are much poorer substrates for biotransformation. One of the most potent ligands for the AhR is the dioxin, 2,3,7,8-tetrachlorodibenzodioxin (TCDD), which is highly recalcitrant to biotransformation (Denison and Nagy, 2003).

In similarity with xenoestrogen-mediated inductions of Vtg via the ER, the inducibility of biotransformation enzymes via the AhR by xenobiotics has been used for biomonitoring. In this regard, enzymatic activities associated with the CYP1As have been the most widely used AhR-related biomarker, particularly an activity that appears highly specific for these CYPs, ethoxyresorufin *O*-deethylase (EROD), which is most often quantified in liver tissue of vertebrates. Elevated activities of EROD in various vertebrates have been associated with exposures to PCBs, dioxins, PAHs, and complex mixtures of these associated with, for example, harbor sediments, municipal effluents, paper mill effluents, refinery effluents, and crude oil spills (Custer et al., 2001; van der Oost et al., 2003; Miller et al., 2005). Invertebrate AhR homologs examined do not bind to ligands similarly to vertebrate AhRs and do not demonstrate protein inductions analogous to those observed in vertebrates (Butler et al., 2001; Hahn, 2002; Chaty et al., 2004). PAH and pHAH toxicities and the potential roles played by their interactions with the AhR will be discussed at various points in subsequent sections of this chapter, and related discussions from a human health standpoint appear in other chapters.

Genomics and Ecotoxicogenomics Advances in "omics"-level technologies for comprehensive interrogation of biological structure, function, and system dynamics continue to revolutionize molecular biology. These advances have permeated many areas of biological research, including toxicology and environmental science. We will briefly describe many of the techniques that are commonly used in these fields, since several omics technologies other than genomics are now in wide use.

Underlying *genomics* advances are very large projects to sequence the entire genomes of various species, such as the Human Genome Project that was completed in 2003 (Little, 2005). Other species that have been completely or largely sequenced include the mouse, rat, cow, dog, chimpanzee, chicken, zebrafish (*Danio rerio*), puffer fish (*Fugu rubripes*), medaka (*Oryzias latipes*), fruit fly (*Drosophila melanogaster*), a sea urchin (*Strongylocentrotus purpuratus*), a soil nematode (*Caenorhabditis elegans*), a yeast (*Saccharomyces cerevisiae*), and rice (*Oryza sativa*). The number of species with fully sequenced and annotated reference genomes continues to expand, as well as the tools available for genomic research (Kim et al., 2013; Louis et al., 2015; various Web sites, including https://www.ncbi.nlm.nih.gov/pubmed/24124405). Although microarray-based platforms to detect single nucleotide polymorphisms (SNP chips) are still commonly used in large epidemiologic cohorts (Ha et al., 2014), most experimental toxicology and environmental science laboratories are using more quantitative, high-resolution sequencing techniques. New genomics technologies offer significantly higher resolution as compared to previous sequencing techniques, which enables increased detection of rare sequence (Cao et al., 2013) and structural variants (Hanscom and Talkowski, 2014) in somatic or germ cells, somatic rearrangements common in cancer (Quek et al., 2014), or previously unrecognized somatic mosaicism (Gajecka, 2016). Collectively, these new sequencing approaches are often referred to as "next-generation sequencing (NGS)," "massively parallel sequencing," or "high-throughput sequencing" (Koboldt et al., 2013, Muzzey et al., 2015). The same sequencing technology employed in whole genome sequencing can be used to sequence short stretches of sequence at high resolution ("amplicon sequencing") (Andersen et al., 2014), or a defined subset of the genome, such as coding regions in "whole exome sequencing" (Ku et al., 2012), or mitochondrial genomes in "mtGenome sequencing" (Ye et al., 2014; Peck et al., 2016). Sequencing technologies are evolving rapidly, leading to reduced costs and effort and making their application to nontraditional models more practical (see review by Goodwin et al., 2016).

In addition to significant advances in genomics, available technology to interrogate the epigenome has rapidly expanded. The epigenome includes mitotically heritable changes in gene function that occur without changes in the DNA sequence (Jaenisch and Bird, 2003). Structural components of the epigenome that control compaction and accessibility of genomic regions include covalent modification of DNA, commonly methylation of the fifth position of cytosines ("DNA methylation"), posttranslational modifications to histone proteins contained within nucleosomes, and chromatin remodeling proteins that alter the three-dimensional structure of chromatin (Callinan and Feinberg, 2006). Although previously measured by sequencing a small number of cloned alleles (Huang et al., 2013), now DNA methylation is more commonly measured in one of two ways (Yong et al., 2016): either in a subset of the genome using DNA methylation microarray techniques, or with next-generation bisulfite sequencing, of individual amplicons, a subset of the genome enriched for methylated DNA ("reduced-representation bisulfite sequencing"), or whole-genome bisulfite sequencing, all of which require prior modification of the DNA with sodium bisulfite. Sodium bisulfite treatment deaminates unmethylated, but not methylated, cytosines to uracils, which are then amplified as thymines as PCR and are detected as sequence changes when compared to the reference sequence (Huang et al., 2013). Posttranslational modifications (PTMs) to histone proteins can be measured locally using chromatin immunoprecipitation (ChIP), which uses antibodies to specific PTMs to enrich the sample for DNA associated with these marks (Rodriguez-Ubreva and Ballestar, 2014), and subsequent PCR of the region of interest; the same approach can be scaled to assess a subset of the genome using microarray technology (ChIP-chip) or genome-wide with next-generation sequencing (ChIP-seq) (Schulz and Haussler, 2104). Newer peptide arrays enable discovery of novel proteins or protein complexes that are recruited to or interact with individual or combinations of histone PTMs (Fuchs et al., 2011; Rothbart et al., 2012).

Genome sequencing set the stage for genome-wide analysis of gene expression ("transcriptomics" to measure gene transcription and "proteomics" to measure gene translation). The platform most commonly used in ecotoxicology is the expression microarray (Neumann and Galvez, 2002; Jyasundara et al., 2015). cDNAs for known genes can be spotted on glass slides, or chips, resulting in microarrays that can be employed to quantify relative levels, that is, expression, of mRNAs for those genes in samples of interest. In recent years, the microarray approach has been largely supplanted by the transcriptomics technique RNA-seq, which is more quantitative and higher resolution, as well as significantly less expensive, laborious, and error-prone than microarrays (Wang et al., 2010). Induced transcription can be distinguished from constitutive transcription in real-time using new techniques that employ the labeled nucleotide bromouridine (Roberts et al., 2015). Also advancing rapidly are related analyses of global changes in proteins (the translation products of mRNAs), referred to as "proteomics," and resulting metabolite profiles (amounts of sugars, lipids, amino acids, etc. in various tissues that are controlled in part by enzyme activities), referred to as "metabolomics." These approaches often employ sophisticated mass-spectrometry techniques (Altelaar et al., 2013). Translation can be measured in real-time, too, using a technique called "ribosome profiling," which employs capture and

sequencing of transcripts undergoing active translation (Brar and Weissman, 2015).

A major complexity in all of these global analyses is the extremely large data sets that arise, for example, when one examines the responses of thousands of genes from organisms exposed to one or more concentrations of a chemical at one or more time points. This has led to the development and rapid expansion of the field of "bioinformatics" that includes the application of sophisticated statistical and computing approaches for revealing biologically meaningful patterns of gene expression, such as relationships to cellular signaling pathways (Del Chierico et al., 2015).

Omics have spread into the science and applications of ecotoxicology, collectively termed ecotoxicogenomics. As is the case for human health–oriented toxicogenomics, ecotoxicogenomics has great potential for elucidating impacts of chemicals of ecological concern and ultimately for playing an important role in Ecological Risk Assessments (ERAs) and regulatory ecotoxicology (Snape et al., 2004; Ankley et al., 2006; Watanabe and Iguchi, 2006). Specific areas to which this emerging field can contribute include prioritization of chemicals investigated in ERAs, identification of modes of action of pollutants, identification of particularly sensitive species and populations, and effect prediction at higher levels of organization. A recent study employed whole-genome sequencing, RNA-seq, and advanced bioinformatics analyses to elucidate molecular mechanisms underlying the rapid evolutionary adaptation of Atlantic killifish (*Fundulus heteroclitus*) to severe pollution (Reid et al., 2016). Epigenome-wide analyses have also permeated ecotoxicology (Vandegehuchte and Janssen et al., 2011; Suarez-Ulloa et al., 2015). As in other areas of ecotoxicology, a major complexity faced by scientists applying omics techniques is the vast array of species of potential concern. This is a particularly problematic issue in ecotoxicogenomics that requires substantial species-specific molecular information. However, as mentioned earlier, the number of ecologically relevant species for which this information is becoming available is expanding rapidly, and is likely to accelerate as more genomes are fully sequenced and tools are refined. Moreover, as information grows, genomics and related approaches hold great promise for identifying appropriate surrogate species for laboratory studies used in basic ecotoxicological research and in support of regulatory ecotoxicology (Benson and Di Giulio, 2006; Van Aggelen et al., 2010).

Protein Damage The study of chemical effects on proteins, particularly enzymes, has a long history in toxicology. Of particular interest within ecotoxicology are the inhibitions of acetylcholinesterase (AChE) by certain pesticides and of delta-aminolevulinic acid dehydratase (ALAD) by lead. AChE degrades the neurotransmitter acetylcholine, and in so doing controls nerve transmission in cholinergic nerve tracts. The widely used organophosphate and carbamate classes of insecticides kill by inhibiting AChE, and this mechanism is operative for "nontarget" organisms including invertebrates, wildlife, and humans. (See Chap. 22, "Toxic Effects of Pesticides," for a detailed discussion of these pesticides and AChE inhibition.) Of particular ecological concern have been the ingestions of AChE-inhibiting insecticides with food items or granular formulations (mistaken as seed or grit) by birds and exposures to aquatic animals from agricultural runoff (Mineau, 1991; Carr et al., 1997; Wilson et al., 2001). In many field studies, effects of these insecticides on mortality, and relationships between AChE inhibition and mortality, have been of primary concern. However, relationships between AChE inhibition and important sublethal impacts such as behavior have also been observed (Sandahl et al., 2005).

ALAD catalyzes the rate-limiting step of heme synthesis, a key component of cytochromes, hemoglobin, and myoglobin, and ALAD activity is very sensitive to inhibition by lead (ATSDR, 1999). This sensitivity has been exploited widely as a biomarker for lead exposure in humans and wildlife. In wildlife, concerns for lead exposure have included ingestion by birds of spent lead shot used in hunting (Kendall et al., 1996), accumulation of lead by wildlife living near highways (Birdsall et al., 1986), and aquatic organisms inhabiting surface waters contaminated by lead from mine runoff and other industrial activities (Schmitt et al., 2005). Many other enzymes have been observed to be inhibited by numerous pollutants. In addition to enzyme inhibition, chemicals can damage proteins in other ways, including oxidative damage as described in section Oxidative Stress, and by forming stable adducts similar to those formed with DNA, described in section DNA Damage.

Oxidative Stress The classic depiction of aerobic respiration shows molecular oxygen (O_2) as the terminal electron acceptor, with its reduction resulting ultimately in water as high-energy intermediates (NADH, $FADH_2$) are oxidized and cellular energy is captured as ATP. This reduction of O_2 to H_2O requires four electrons that are sequentially added; this process is tightly coupled so that the one-, two-, and three-electron intermediates are released at low amounts (less than 0.1% of O_2 inspired; Fridovich, 2004). These intermediates are, in sequence, the superoxide anion radical ($O_2^{\bullet-}$), hydrogen peroxide (H_2O_2), and the hydroxyl radical ($^{\bullet}OH$). This tight coupling is fortunate because these intermediates, produced during aerobic respiration and other O_2-consuming or O_2-producing processes (such as photosynthesis and CYP-mediated biotransformations), are potentially deleterious products that can indiscriminately damage cellular components; hence, they are referred to as "reactive oxygen species" (ROS); see Chap. 3, "Mechanisms of Toxicity." Some ROS, including $O_2^{\bullet-}$ and $^{\bullet}OH$, are free radicals, that is, they possess an unpaired electron; among ROS, $^{\bullet}OH$ is particularly reactive and toxic. In order to defend themselves from the damaging effects of ROS, all aerobic organisms have evolved complex antioxidant defense systems that include enzymatic and nonenzymatic components (Halliwell and Gutteridge, 1999). Antioxidant enzymes include superoxide dismutases that convert $O_2^{\bullet-}$ to H_2O_2, catalases and peroxidases that detoxify peroxides including H_2O_2, and enzymes involved in the production and maintenance of reduced glutathione (GSH) such as glutamate–cysteine ligase (GCL) and glutathione reductase (GR). Low-molecular-weight, nonenzymatic antioxidants include vitamins A, C, and E, and GSH.

Oxidative stress has been defined as "a disturbance in the prooxidant–antioxidant balance in favor of the former, leading to potential damage" (Sies and Cadenas, 1985)—that is, the point at which the production of ROS exceeds the capacity of antioxidants to prevent damage. Numerous environmental contaminants can act as prooxidants and enhance the production of ROS. The resulting oxidative damage can account wholly or partially for toxicity (Halliwell and Gutteridge, 1999). Mechanisms by which chemicals can enhance ROS production include redox cycling, interactions with electron transport chains (notably in mitochondria, microsomes, or chloroplasts), and photosensitization.

Redox cycling is perhaps the most common mechanism by which a diverse array of chemicals including many environmental pollutants generates intracellular ROS. Redox cycling chemicals include diphenols and quinones, nitroaromatics and azo compounds, aromatic hydroxylamines, bipyridyliums, and certain metal chelates, particularly of copper and iron (Di Giulio et al., 1989; Halliwell and Gutteridge, 1999). These include compounds of broad industrial use, many pesticides, ubiquitous elements, and metabolic products of numerous pollutants. In the redox cycle,

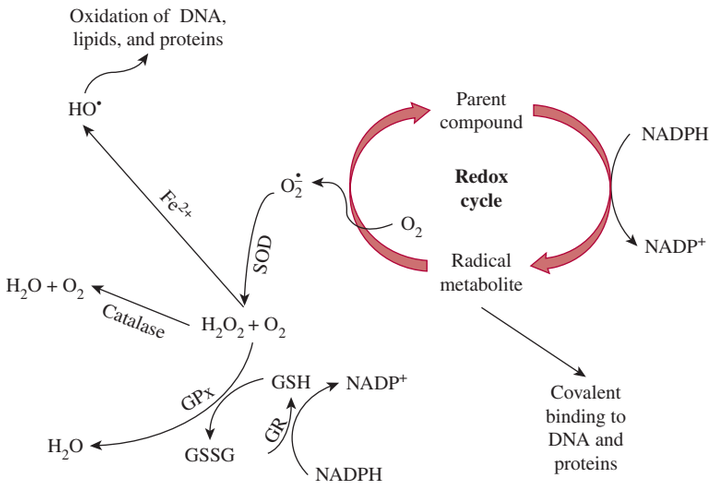

Figure 30-8. *Overview of oxidative stress, including reactive oxygen species stimulation initially by redox cycling, key antioxidant defenses, and potential deleterious biochemical effects.* "Parent compound" in redox cycle could include a number of chemicals such as quinones, nitroaromatics, azo dyes, paraquat and diquat, and transition metal chelates.

the parent compound accepts an electron from a reduced cofactor, such as NADH or NADPH; this reaction is typically catalyzed by a reductase such as xanthine oxidase or cytochrome P450 reductase (Kappus, 1986). In the presence of O_2, the unpaired electron of the radical metabolite is donated to O_2, yielding $O_2^{\bullet}$ and regenerating the parent compound; importantly, the parent compound can repeat this cycle until it is cleared or metabolized to an inactive product. In the course of each redox cycle, two potentially deleterious events occur—a high-energy reducing equivalent is expended (e.g., the oxidation of NADPH to $NADP^+$) and an oxygen radical is produced. A generalized redox cycle that includes associations with cellular toxicities and antioxidant defenses comprises Fig. 30-8.

Additionally, pHAH AhR ligands such as coplanar PCBs and TCDD can enhance ROS production, possibly by inducing CYP1A activity and concomitantly interfering with electron flow mediated by these enzymes (Schlezinger and Stegeman, 2001). PAHs can also upregulate CYP1A and can enhance the production of ROS-generating redox-active quinone metabolites, in contrast to uncoupling mechanisms proposed for pHAHs; Nebert et al. (2000) discuss potential mechanisms by which AhR agonists can produce oxidative stress. The herbicide paraquat is phytotoxic due to interference with chloroplast electron transport. Interestingly, it is a very potent lung toxicant because of its specific uptake by this tissue and subsequent redox cycling (Halliwell and Gutteridge, 1999). Another important mechanism particularly significant in aquatic systems is photosensitization. Ultraviolet (UV) radiation (specifically UVB and UVA) can penetrate surface waters to depths dependent on the wavelength of the radiation and the clarity of the water. The UV radiation generates ROS and other free radicals via excitation of photosensitizing chemicals, including common pollutants of aquatic systems (Larson and Weber, 1994). For example, due to photosensitization, many PAHs are orders of magnitude more acutely toxic to aquatic organisms in the presence of UV radiation than in its absence (Arfsten et al., 1996; Ankley et al., 1997). The ecological relevance of photosensitization, however, is controversial (McDonald and Chapman, 2002).

As noted, ROS are generally indiscriminant molecules and can potentially damage any cellular component. Well-characterized biochemical impacts of ROS include oxidations of unsaturated lipid components of membranes ("lipid peroxidation"), oxidations of amino acids and proteins (resulting in, e.g., the addition of carbonyl groups), and DNA oxidations resulting in products such as 8-hydroxy-guanosine and thyme glycol (Halliwell and Gutteridge, 1999). Another important impact is perturbed redox status (Schafer and Buettner, 2001). Healthy cells typically maintain high ratios of cofactors in their reduced, high-energy state relative to their oxidized state (e.g., NADH/NAD^+, NADPH/$NADP^+$, and GSH/GSSG), as the reduced forms are those most employed, for example, for energy production, biosynthesis, and antioxidant defense. The ROS can drive redox status to a more oxidized state by several direct and indirect mechanisms, potentially reducing cell viability. These ROS-mediated impacts and others have been associated with a number of human diseases including atherosclerosis, arthritis, cancer, and neurodegenerative diseases such as Alzheimer disease, Parkinson disease, and amyotrophic lateral sclerosis (Halliwell and Gutteridge, 1999). With the exception of cancer (see Cancer section), the role of ROS in specific diseases in wildlife has received little attention. However, numerous studies have documented oxidative stress–mediated biochemical and cellular effects in wildlife associated with environmental contamination (Winston and Di Giulio, 1991; Bainy et al., 1996; Livingstone, 2001; van der Oost et al., 2003; Dorval et al., 2005; Birnie-Gauvin et al., 2017). As with humans and various animal models for human disease, it is reasonable to assume that oxidative stress comprises an important mechanism accounting in part for the toxicity of diverse pollutants to free-living organisms. Also, oxidative stress is involved in the effects of air pollutants on plants and likely plays a role in forest diebacks observed downwind of industrialized areas (Richardson et al., 1989; Hippeli and Elstner, 1996).

DNA Damage The importance of DNA as a molecular target in toxicology is indicated by the devotion of Chap. 9, "Genetic Toxicology," of this text to genetic toxicology. As indicated, perhaps the most pressing human health issue associated with xenobiotic–DNA interactions is cancer. Cancer is also an important health outcome associated with chemical exposures in wildlife, particularly for bottom-dwelling fish, as discussed in the section "Cancer" later in this chapter. Of greater concern in ecotoxicology versus human health are other, multigenerational effects of pollutants on genetic structures and resulting phenotypes of populations and communities, through both direct effects on DNA (mutations)

and indirect effects (selection); this topic is discussed in the section "Toxicant Effects: Population."

Chemical contaminants can damage DNA through several mechanisms, including by the formation of DNA–xenobiotic adducts, by causing strand breaks, and by oxidations of DNA bases. In the context of ecotoxicology, the most widely studied form of damage has been the formation of stable DNA adducts, particularly by PAHs. In order to form these adducts, PAHs must first be activated to reactive metabolites by enzyme systems such as the cytochrome P450s. The bulk of PAHs metabolized to various oxidized products (such as phenols, diols, and epoxides) is subsequently conjugated by phase II enzymes (such as GSH, sulfate, and glucuronosyl transferases; see Chap. 6, "Biotransformation of Xenobiotics"); however, some fraction can react with DNA, mainly through covalent bonding with DNA bases. The most studied example of this is benzo(*a*)pyrene (BaP), which can be metabolized to the highly reactive benzo(*a*)pyrene diol epoxide (BPDE) that can bond to DNA. In field studies, the resulting large adducts of DNA with BPDE and other activated PAHs and related compounds can be measured with the highly sensitive ^{32}P-postlabeling assay (Phillips, 1997). This technique has been used extensively to monitor DNA adducts in benthic fish and bivalves inhabiting systems contaminated with hydrocarbons, particularly PAHs (Maccubbin, 1994; Reichert et al., 1998; Shugart, 2000; Amat et al., 2004). Other forms of DNA damage that have been investigated in ecotoxicological studies include DNA strand breaks and oxidized DNA bases (Shugart, 2000; Malins et al., 2006).

Once DNA damage has occurred, whether from chemical exposures or other causes (respiration, UV radiation, viral interactions, normal wear and tear), several subsequent outcomes can occur, including the following: the damage can be properly repaired, the damage can lead to cell death, or a resulting change in DNA structure (base sequence) can become fixed and passed on to daughter cells, that is, mutation occurs. Complex DNA repair systems have been elucidated in prokaryotic and eukaryotic organisms (see Chap. 8, "Chemical Carcinogenesis," and Chap. 9, "Genetic Toxicology"), and while these systems have received relatively little attention in species of ecological relevance, it is a safe assumption that these conserved systems are qualitatively similar across diverse phyla. Overall, these systems exhibit a remarkable capacity for surveying the cellular genome, detecting damage such as oxidations, adducts, and strand breaks, and repairing the damage by, for example, removing a damaged base and replacing it with the correct base. However, misrepair does sometime occur, with the result that an incorrect base is incorporated. Depending on the gene involved and the site within the gene, this change may lead to cell death, or may result in a mutation that may have no effect (occurs at noncritical base sequence) or one that leads to functional change in the protein coded by the gene. Some chemicals cause cancer by mutating genes that play pivotal roles in cellular growth and differentiation, particularly oncogenes and tumor suppressor genes. Examples of discoveries of activated genes (in liver tumors) in field studies include the *K-ras* oncogene in tomcod (*Microgadus tomcod*) from the Hudson River, New York (Wirgin et al., 1989), and in winter flounder (*Pseudopleuronectes americanus*) collected from Boston Harbor (McMahon et al., 1990), and the retinoblastoma (*Rb*) tumor suppressor gene in the marine flatfish, dab (*Limanda limanda*), from the United Kingdom (du Corbier et al., 2005).

Cellular, Tissue, and Organ Effects

Cells Cellular organelles that have received attention as targets in species of ecological interest include mitochondria, lysosomes, and nuclei. Most free-living organisms routinely experience energy deficits. For example, food resources are often highly depleted during the winter for many animals, which adapt by conserving energy (by hibernating or lowering metabolism) or by storing energy beforehand (as the case for many migratory birds). Thus, effects of pollutants on mitochondrial energy metabolism can be of particular importance to wildlife. For example, Sokolova and coworkers (Sokolova, 2004; Cherkasov et al., 2006) have elegantly described the effects of cadmium on several aspects of mitochondrial function in isolated gill and hepatopancreas cells from the eastern oyster (*Crassostrea virginica*), and noted a marked synergy between the metal and increasing environmental temperatures. Lysosomes are involved in the degradation of damaged organelles and proteins, and also sequester a wide variety of environmental contaminants, including metals, PAHs, and nanoparticles (Moore, 2006). The accumulation of xenobiotics by lysosomes can elicit membrane damage, or "membrane instability," which has been used as an early warning measure of pathological chemical effects in both invertebrates and vertebrates (Hwang et al., 2002; Kohler et al., 2002; Moore et al., 2006).

In addition to specific damage to DNA bases described above, chemical effects on nuclei have been examined in ecological contexts with additional techniques. Micronuclei are chromosomal fragments that are not incorporated into the nucleus at cell division, and chemical exposures can markedly increase their frequency. Elevated micronuclei numbers have been observed, for example, in fish erythrocytes from polluted coastal sites in California (Hose et al., 1987) and in hemocytes in clams from a PCB-polluted harbor in Massachusetts (Dopp et al., 1996). Also, a standardized higher plant (*Tradescantia*) assay for micronuclei has been used for monitoring air pollution (Solenska et al., 2006). A cell-based assay that has been used widely in environmental applications is the comet assay. In this assay, cells are imbedded in agarose, lysed, and subjected to gel electrophoresis, and the features of the resulting "comet's tail" on the gel used to assess DNA damage. With appropriate manipulations, the comet assay can be employed to detect and distinguish among a variety of genotoxicities including strand breaks, oxidative damage, and adducts (Moller, 2006). It has been used in a variety of field applications, particularly with bivalves (Steinert, 1999; Nigro et al., 2006), fish (Klobicar et al., 2010), and mice (Husby and McBee, 1999).

Histopathology The detailed microscopic analysis of the structure of cells and tissues can provide important links among chemical exposures, cellular targets and mechanisms, and effects at the organismal level (Hinton, 1994). Moreover, the determination that tissue damage has occurred as demonstrated by histopathological analysis is extremely useful for inferring that a significant deleterious effect has occurred. However, the substantial expertise required for proper histopathological analyses of this nature and the oftentimes time- and labor-intensive nature of these analyses has perhaps limited the application of this powerful approach in ecotoxicological contexts. Nevertheless, histopathological analysis has played an important role in confirming chemically mediated tissue damage in numerous laboratory and field studies. For example, Pacheco and Santos (2002) integrated histopathological analysis with biochemical studies of the effects of various environmental contaminants on the European eel (*Anguilla anguilla*), and Devlin (2006) similarly incorporated this approach in studies of the effects of methylmercury in fathead minnows (*Pimephales promelas*). Handy et al. (2002) relied on histopathology in a study of fish health in rivers in southern England. Wester et al. (2002) reviewed the application and potential contributions of histopathology in aquatic toxicology,

particularly in the context of small fish models. In subsequent sections concerning organismal-level impacts, other examples of the use of histopathology will be provided.

Target Organs Descriptions of chemical impacts on all organ systems of the myriad species relevant to ecotoxicology are beyond the scope of this chapter. Other chapters in this volume address key target organs in the mammalian context, and much of this is relevant to other vertebrates. Target organ toxicology is also the subject of comprehensive reviews by Schlenk and Benson (2001) concerning marine and freshwater fish, and by Gardner and Oberdorster (2005) concerning reptiles. Relevant information in marine mammals was reviewed in Vos et al. (2002). Although we are unaware of similar reviews for birds or invertebrates, understanding target organ toxicity can be crucial for these taxa as in the recent case of widespread renal poisoning of vultures exposed to the veterinary drug diclofenac during scavenging on cattle carcasses (Oaks et al., 2004). Further, the unique properties of the avian respiratory system and its utility for investigating respiratory system toxicity and air pollution were reviewed by Brown et al. (1997).

Another important target organ in ecotoxicology that is not covered elsewhere in this text is the respiratory organ of nonmammalian aquatic vertebrates and many invertebrates, the gill; gills of fish have received the most attention as targets of toxicants. The gill epithelium is the major site of gas exchange, ionic regulation, acid–base balance, and nitrogenous waste excretions for fish and other aquatic animals (Evans, 1987). Gills are immersed in a major exposure medium for these animals (surface water), so metabolically active epithelial cells are in direct contact with this medium. They also receive blood supply directly from the heart, through the ventral aorta. Thus, it is not surprising that gills comprise a very important target for many environmental pollutants, due to their critical physiological functions, central position in blood circulation pathways, and intimate relationship with the environment. The basic structure of fish gills is composed of branchial arches from which extend numerous filaments; from the filaments extend the lamellae (Wendelaar Bonga and Lock, 2008). The lamellae are covered by a layer of epithelial cells that function in gas exchange, whereas the filament epithelium is dominated by other cell types, including pavement cells, mucous cells, and chloride cells; chloride cells are the primary location for ATPase activity and ion channels involved in ion transport.

Common structural lesions in gills caused by a diverse array of chemicals include cell death (via necrosis and apoptosis), rupture of the epithelium, hyperplasia and hypertrophy of various cell populations that can lead to lamellar fusion, epithelial swelling, and lifting of the respiratory epithelium from the underlying tissue (Wendelaar Bonga and Lock, 2008). Chloride cells have received particular attention due to their key role in ionic homeostasis. For example, metals such as cadmium, copper, lead, silver, and zinc have been shown to interfere with their function in ion transport. In some cases, this may be due to inhibition of ATPase activities and/or increased membrane permeability (Spry and Wood, 1985; Wendelaar Bonga and Lock, 1992; Li et al., 1998; Rogers et al., 2003; Bury, 2005). The stress response, which results in elevated blood concentrations of epinephrine and cortisol, and associated responses such as increased cardiac output and elevated blood pressure, can also perturb ionic balance by promoting passive loss of ions such as Na^+ and Cl^- (Wendelaar Bonga and Lock, 2008). A variety of contaminants have been shown to evoke the stress response in fish, sometimes concomitantly with perturbations in ionic balance (Hontela, 1997; Webb and Wood, 1998; Chowdhury et al., 2004). Also, gill damage appears to be the primary cause of the acute toxicity of PAH-mediated phototoxicity in fish (see the section "Oxidative Stress"). Weinstein et al. (1997) reported histopathological impacts of UV + fluoranthene in gills of fathead minnows including severe damage to mucosal cells, inflammation, and apparent accumulation of lipid peroxidation products; these effects likely resulted in respiratory stress and lethality. This study elegantly demonstrates a progression from biochemical mechanism (oxidative stress) to target organ damage (gill respiration) to an important organismal impact (death). Mortality and important sublethal organismal impacts that have received substantial attention among ecotoxicologists are covered in the following section.

Organismal Effects

Mortality In similarity with impacts on human health, chemical pollution of the environment does not in most cases attain levels sufficient to outrightly kill wildlife. Concern in the ecotoxicological context is overall more for long-term, chronic impacts on organismal variables such as survival, reproduction and development, behavior, and disease susceptibility, and how such impacts translate to impacts at population and higher levels of organization. However, numerous cases of wildlife mortalities (particularly birds and fish) due to exposures to chemical pollution have been observed, including cases associated with chronic oil discharges (Wiese and Robertson, 2004) and major oil releases from events such as the Exxon Valdez tanker wreck in Alaska (Peterson et al., 2003) and the 1991 Gulf War (Evans et al., 1993), lead from spent shot (Clark and Scheuhammer, 2003) and mines (Henny, 2003), and pesticide exposures (Mineau et al., 1999).The ingestion of lead ammunition fragments when scavenging on carcasses results in fatal poisonings to endangered California condors (Wiemeyer et al., 1988; Cade, 2007). In this instance, death of an endangered individual condor was relevant. Similarly, oriental white-backed vultures scavenging on cattle carcasses in South Asia consume enough of the veterinary anti-inflammatory drug, diclofenac, to cause fatal kidney failure (Oaks et al., 2004; Balmford, 2013). While not a direct toxic chemical effect, hypoxia can be an important cause of fish and invertebrate mortality in aquatic systems; anthropogenic inputs of nutrients associated with sewage or fertilizers that enhance the growth of phytoplankton can cause or exacerbate hypoxia (Paerl et al., 1999; Wu, 2002). While direct mortality may not be a commonplace effect of toxic chemicals in natural systems, mortality comprises a major endpoint in toxicity testing, discussed in section "Population."

Reproduction and Development Impacts on reproduction and development comprise perhaps the greatest concern among potential sublethal effects of xenobiotics on animals inhabiting natural systems. This is due to sensitivities of the physiological processes involved that have been described for a number of pollutants, and the importance of reproduction and development to population dynamics, a key ecological concern. Moreover, the discovery of the effects of some organochlorine insecticides on avian reproduction (particularly eggshell thinning) and resulting population crashes of several predatory bird species, and the public's awareness through the publication of Carson's *Silent Spring* in 1962, can be associated with the birth of ecotoxicology. Concern for reproductive and developmental effects has increased in recent years, with the widespread detection of endocrine disruptors in the environment and the recognition of the inherent sensitivity of the developing organism.

A variety of environmental contaminants have been associated with reproductive and/or developmental effects in wildlife populations, with this association supported by controlled laboratory studies. Chlorinated hydrocarbons have continued to generate concerns, although many (DDT and other insecticides, and PCBs) have had

their production and use sharply curtailed. For example, DDT, its major metabolite in birds (DDE), and PCBs have been associated with reproductive and developmental impacts in bird populations in the Great Lakes, southern California, the Puget Sound, and the Arctic (Fry, 1995; Custer et al., 1999; Bustnes et al., 2005). Also, alligators (*Alligator mississippiensis*) inhabiting a DDT-polluted lake in Florida have exhibited reproductive and developmental perturbations (Guillette et al., 2000). Evidence also indicates that PCBs impact marine mammal reproduction, including that of bottlenose dolphins (*Tursiops truncatus*) (Schwacke et al., 2002; Wells et al., 2005).

Deleterious impacts on fish reproduction have been associated with environmental exposures to a number of contaminants. Case studies include PAHs (and other chemicals) accumulated in sediments in urban areas and harbors in the Puget Sound (Johnson et al., 1993) and northeastern United States (Johnson et al., 1994) or associated with oil spills such as the Exxon Valdez (Sol et al., 2000) and the Deepwater Horizon spill (Xu et al., 2016). Other examples include effluents from bleached paper mills in various locations, including Canada (Munkittrick et al., 1991), and selenium, for example, emanating from coal-fired power plant fly ash stored near freshwater lakes (Lemly, 2002) or in streams due to coal mine runoff (Holm et al., 2005). Notably, selenium produced severe developmental effects in water birds feeding in a created wetland in central California (Kesterson National Wildlife Refuge) that concentrated naturally occurring selenium (Ohlendorf, 2002). Additionally, severe developmental anomalies have also been observed in natural populations of marine gastropods exposed to tributyltin (TBT), which has been used extensively as an antifouling paint on ship hulls (Ruiz et al., 2005).

The developmental effects of dioxins (TCDD) and coplanar PCBs on vertebrate development have received substantial attention. To some extent, this work was motivated by analyses that indicated that these compounds were responsible for population crashes of Great Lakes' fisheries (particularly lake trout, *Salvelinus namaycush*, in Lake Ontario) in the 1950s and 1960s, as well as for developmental impacts on other wildlife, particularly piscivorous birds and mammals in the region (Gilbertson et al., 1991; Cook et al., 2003). Laboratory investigations, largely with fish and bird models, have shown that embryo development is very sensitive to these compounds, and such effects likely underlaid the population crashes (Fairbrother et al., 1999; Cook et al., 2003). These investigations have included elegant mechanistic studies that revealed cardiac development was particularly sensitive to these chemicals, and concluded that developmental perturbations are largely receptor mediated, that is, they are dependent on binding of the chemical (such as TCDD) with the AhR described earlier in this chapter (Hankinson, 1995; Heid et al., 2001; Tanguay et al., 2003; Antkiewicz et al., 2005). Much of the more recent work in this area has been done with zebrafish (*D. rerio*), a powerful model for molecular and developmental toxicology due to ease of visually examining development through a clear chorion, rapid development (approximately 4 days from fertilization to hatch), and abundant genetic information, including gene sequences (Carney et al., 2006). For example, with a known gene sequence, one can design morpholinos to block translation of specific mRNAs; morpholinos are oligonucleotides with a modified "backbone" that renders them stable (resistant to DNA/RNAase activities) and thus able to transiently block translation of specific protein targets. Carney et al. (2004) employed morpholinos to knock down AhR translation in zebrafish embryos, which greatly reduced the developmental toxicity of TCDD, confirming the role of the AhR in dioxin toxicity. Morpholinos were also employed to investigate the role of CYP1A; for example, its upregulation via TCDD activation of the AhR could enhance oxidative stress. Teraoka et al. (2003) observed marked reductions of TCDD toxicity with either AhR or CYP1A morpholinos, while Carney et al. (2004) observed protection with the AhR but not the CYP1A morpholino. While the role of CYP1A in dioxin effects on development remains unclear, pathways downstream of the AhR other than CYP1A are likely involved.

Similar concerns have emerged for the developmental effects of PAHs, particularly in fish. Hydrocarbons, in large part PAHs, associated with oil spills, contaminated sediments, paper mill effluents, and creosote used for wood treatment have profound developmental effects in fish embryos (Billiard et al., 1999; Carls et al., 1999; Meyer et al., 2002). In many cases, the effects observed visually appear similar to those observed in fish embryos exposed to dioxins and coplanar PCBs, and include malformed hearts ("tube heart"), craniofacial deformities, hemorrhaging, and edema of the pericardium and yolk sac, the latter resulting in a distended, faintly blue yolk sac and hence a name given to this syndrome—"blue sac disease" (Spitsbergen et al., 1991). The mechanisms by which PAHs produce this effect are unresolved, and likely include more than a single mechanism—not surprising in light of the myriad of chemicals comprising hydrocarbon/PAH mixtures in the environment. In some cases, effects appear to be AHR-independent. Incardona et al. (2005) concluded in studies with zebrafish and employing morpholinos that in weathered crude oil, tricyclic PAHs (such as phenanthrene and dibenzothiophene [DBT], the latter a sulfur-substituted PAH) accounted for the bulk of cardiovascular teratogenesis, and rather than mediating toxicity, the AHR–CYP1A pathway afforded some protection. Wassenberg and Di Giulio (2004a) and Wassenberg et al. (2005) observed marked synergies in the developmental toxicity to killifish (*Fundulus heteroclitus*) embryos between higher molecular weight PAHs that are AHR agonists (BaP and BNF) and PAHs that inhibit CYP1A (α-naphthoflavone [ANF], fluoranthene, DBT, and carbazole—a nitrogen-substituted PAH). Also, ANF enhanced the toxicity of a water-based extract of sediments contaminated with weathered creosote (Wassenberg and Di Giulio, 2004b). In subsequent studies with zebrafish embryos investigating the synergistic toxicity of BNF and ANF, the AHR morpholino provided protection, while the CYP1A morpholino enhanced toxicity (Billiard et al., 2006). Collectively, these PAH studies suggest that in the context of embryo toxicity, CYP1A plays a protective role, presumably by mediating metabolism and clearance of these metabolically labile compounds. This is in contrast to the metabolism-resistant dioxin-like compounds, where CYP1A either appears to play a role in mediating toxicity or has no effect. For some PAHs, such as lower molecular weight (tricyclic) PAHs that have little or no activity as AHR ligands, developmental toxicity appears AHR-independent, while the developmental toxicity of some higher molecular weight PAHs that are AHR agonists appears in part AHR-mediated. In addition, oxidative stress may play a role in the developmental toxicity of some PAHs to fish embryos (Bauder et al., 2005). PAHs comprise an important class of contaminants whose widespread occurrence is broadly associated with urbanization, population growth, and use of fossil fuels (Van Metre and Mahler, 2005).

Developmental abnormalities arising from toxicant exposure are also of concern for invertebrate species. As an important example already mentioned, antifouling agents in paints applied to ship hulls leach into coastal waters, causing widespread imposex in many marine snails (Leung et al., 2006). Acting as endocrine disrupters, organotin compounds cause male characteristics such as a penis or vas deferens to develop in females. Often this imposition of male characteristics on females results in an individual snail's

inability to reproduce and eventual collapse of impacted snail populations (Saavedra Alvarez and Ellis, 1990; Leung et al., 2006).

Contaminant effects on development are often difficult to discern in field studies due to the small size of embryos and the fact that developmental impact generally is lethal or greatly reduced survival. However, early life stages of most organisms are generally more sensitive to xenobiotics than other life stages; thus, developmental impacts merit careful attention by ecotoxicologists.

Disease Susceptibility Disease plays an important role in regulating and sometimes seriously impacting populations of free-living organisms. Of great concern are interactions between disease organisms and environmental contaminants, particularly potential impacts of chemicals on immune systems that render organisms more susceptible to disease. The question is often raised about how chemical pollution elevates the role of disease in population viability and dynamics.

Both field observational and laboratory experimental studies motivate this concern. For example, forensic evidence suggested that pHAHs such as dioxins and PCBs may have played a role in mass mortalities of seals and other marine mammals in the Baltic Sea that were directly attributed to viral infections (Ross et al., 1996). Captive harbor seals (*Phoca vitulina*) fed fish from the Baltic Sea displayed a number of immune system deficits relative to seals fed fish from uncontaminated Atlantic Ocean sites, including impaired natural killer (NK) cell activity, in vitro T-lymphocyte function, antigen-specific in vitro lymphocyte proliferative responses, and in vivo delayed-type hypersensitivity and antibody responses to ovalbumin. These effects were correlated with greater concentrations of TCDD equivalents in fish from the Baltic Sea. In a case–control study using long-term data from studies of marine mammal strandings in the United Kingdom, Hall et al. (2006) concluded that each 1 mg/kg increase in total PCB concentrations in blubber resulted in an average increase in mortality due to infectious disease of 2% in harbor porpoises (*Phocoena phocoena*). In a study of free-ranging logger-head sea turtles (*Caretta caretta*) collected in North Carolina, Keller et al. (2006) observed significant correlations between selected immune responses (lysozyme activity and lymphocyte proliferation) and concentrations of PCBs and chlorinated insecticides (DDE and chlordanes); these correlations were supported by in vitro studies with these chemicals in isolated turtle leukocytes. Similarly, Auffret et al. (2006) observed responses associated with immunosuppression in mussels (*Mytilus galloprovincialis*) that generally tracked chemical pollution gradients in the western Mediterranean Sea. Using available laboratory and field data, Loge et al. (2005) developed a model to assess the effects of environmental stressors, including chemicals, on disease susceptibility in migrant juvenile salmon in the Columbia River Basin, Washington. They concluded that chemical and nonchemical stressors contributed equally to disease-induced mortalities that were predicted to range from 3% to 18% of the population, depending on residence time.

Numerous laboratory studies have demonstrated chemical impacts on immune systems in animals of ecological relevance. These include effects of pesticides on amphibians (Albert et al., 2007), PCBs on channel catfish (*Ictalurus punctatus*) (Rice and Schlenk, 1995), heavy metals on rainbow trout (Sanchez-Dardon et al., 1999), PAHs on bivalves (Wootton et al., 2003), and flame retardants (polybrominated diphenyl ethers [PBDEs]) on American kestrels (*Falco sparverius*) (Fernie et al., 2005). Fairbrother et al. (2004) reviewed the literature concerning effects of chemicals on immune systems of birds, emphasizing potential impacts on wildlife species, and Carlson and Zelikoff (2008) performed a similar review for fish. The potential effects of chemicals on immune function and disease susceptibility in wildlife is clearly a very important subject in ecotoxicology and one likely to see significant advances in the near future as powerful genomic tools become more available for representative species.

Behavior The impacts of chemicals on animal behavior have received significant attention among ecotoxicologists. Relatively subtle effects on behaviors associated with, for example, mating and reproduction, foraging, predator–prey interactions, preference/avoidance of contaminated areas, and migration have potentially important ramifications for population dynamics. However, difficulties in objective quantifications of behaviors and laboratory to field extrapolations appear to have limited the application of this area to ecological risk assessments (ERAs), and by extension, perhaps to funds available for basic research. In some cases, however, biochemical mechanisms underlying behavioral effects have been elucidated that may assist with these issues and provide useful biomarkers for behavioral toxicants in field studies.

As noted by Rand (1985), chemicals causing behavioral effects in wildlife are often known from mammalian studies to be neurotoxicants. For example, in an early study, Grue et al. (1982) noted reduced nest attentiveness in female starlings dosed with the AChE-inhibiting organophosphate insecticide dicrotophos; this study took advantage of the relative ease of attracting wild starlings to artificial nest boxes that is advantageous for detailed studies, a phenomenon that has been employed in subsequent avian ecotoxicological studies (Parker and Goldstein, 2000). Grue et al. (1997) and Walker (2003) reviewed the behavioral effects in birds of these and other neurotoxic insecticides.

Behavioral effects of insecticides have also been observed in fish. For example, Scholz et al. (2000) reported adverse impacts of the organophosphate diazinon on olfactory-mediated behaviors such as the alarm response and homing in the Chinook salmon (*Oncorhynchus tshawytscha*), and Sandahl et al. (2005) observed similar thresholds for the effects of another organophosphate (chlorpyrifos) on swimming and feeding behaviors and on AChE inhibition in coho salmon (*O. kistich*). The effects of pollutants, including pesticides, on fish behavior were reviewed by Scott and Sloman (2004).

Mercury, particularly as methylmercury, comprises another potent neurotoxicant that has been shown to perturb behavior in wildlife. For example, golden shiners (*Notemigonus crysoleucas*) fed diets containing methylmercury that resulted in tissue mercury concentrations consistent with those observed in this species in northern U.S. lakes exhibited perturbed predator avoidance behaviors (Webber and Haines, 2003). In a study employing fish captured in the field and brought into the laboratory for behavioral analysis, Smith and Weis (1997) observed that killifish captured from a mercury-polluted tidal creek in New Jersey exhibited reduced feeding activity and greater mortality due to predation than killifish from an uncontaminated site. Using mercury concentrations in feathers as a marker for exposure, Heath and Frederick (2005) observed a negative correlation between mercury exposure and nesting activity among White Ibises (*Eudocimus albus*) in the Florida Everglades that may be related to behavioral effects. In studies with wild mink (*Mustela vison*) collected in Canada, Basu et al. (2005) observed significant correlations between mercury concentrations in brains and densities of neurochemical receptors (cholinergic and dopaminergic) associated with animal behavior. The effects of mercury on wildlife, including behavioral impacts, were reviewed by Wolfe et al. (1998).

Environmental contaminants not generally thought of as neurotoxicants have also been shown to perturb behavior. For example,

cadmium and copper have been shown to impact olfactory neurons and associated behaviors (preference/avoidance to chemicals, including pheromones) in several fish species (Saucier et al., 1991; Baker and Montgomery, 2001; Baldwin et al., 2003; Williams et al., 2016). Copper exposure in zebrafish also led to loss of neurons in the peripheral mechanosensory system ("lateral line"), which could lead to altered behaviors associated with schooling, predator avoidance, and rheotaxis (physical alignment of fish in a current) (Linbo et al., 2006). Carvalho and Tillitt (2004) reported loss of retinal ganglion cells in rainbow trout exposed to TCDD; these cells link the eye with the brain, and in this study deficits in visual acuity and prey capture rates were noted in TCDD-exposed fish. Clearly, numerous mechanisms of chemical toxicity can result in behavioral impacts, including direct toxicity to neurons, alterations in hormones that modulate behaviors, and impaired energy metabolism. In some cases, impaired behavior may comprise a sublethal impact with substantive ecological consequence (Scott and Sloman, 2004).

Cancer Beginning in the 1960s, numerous cases of cancer epizootics in wildlife that are associated with chemical pollution, particularly in specific fish populations, have been reported in North America and northern Europe (Harshbarger and Clark, 1990; Vethaak, 1992). As in humans, cancer in these animals occurs largely in relatively older age classes and therefore is oftentimes considered a disease unlikely to directly impact population dynamics or other ecological parameters. However, this may not always be the case, particularly in species that require many years to attain sexual maturity and/or have low reproductive rates. In any event, the occurrence of high incidences of cancer in wildlife populations raises serious concerns for environmental quality at those locations experiencing these epizootics. For these reasons, as well as for concerns for human health in these areas, and the advantages of alternative models such as fish for understanding chemical carcinogenesis, these epizootics have motivated substantial research in several areas relevant to human health and ecotoxicology.

In field studies of cancer outbreaks in aquatic and marine systems, typically only selected species exhibit elevated cancer rates associated with chemical contamination. A major contributor to this differential cancer susceptibility in wild fish populations is clearly lifestyle; benthic (bottom-dwelling) species such as brown bullhead (*Ameriurus nebulosus*) and white sucker (*Catostomus commersoni*) in freshwater systems, and English sole (*Parophrys vetulus*) and winter flounder (*P. americanus*) in marine systems generally exhibit the highest cancer rates in polluted systems (Baumann, 1998). The bulk of chemicals in these systems associated with cancer epizootics, such as PAHs, PCBs, and other halogenated compounds, reside in sediments; benthic fish live in contact with these sediments and prey in large measure on other benthic organisms. Thus, benthic fish experience greater exposures to carcinogens than other species in these systems. Inherent biological differences may also play a role in species susceptibilities to chemical carcinogenesis; for example, laboratory studies have revealed marked differences among fish species in their abilities to activate PAH procarcinogens to DNA adduct-forming metabolite as well as to detoxify them through phase II metabolism (Collier et al., 1992; Hasspieler et al., 1994; Ploch et al., 1998).

In their analysis of cancer epizootics in fish, Harshbarger and Clark (1990) concluded that cancers of the liver (hepatocellular neoplasms) had the strongest associations with chemical pollution, although cancers have been observed in other tissues in wild fish as well (Ostrander and Rotchell, 2005). PAHs appear to be the most implicated class of carcinogens associated with liver neoplasms in fish cancer epizootics. Studies implicating a key role for PAHs (and key PAH sources) include English sole in the Puget Sound (various urban and industrial sources; Malins et al., 1987), brown bullhead in the Black River, Ohio (a coal-coking facility; Baumann and Harshbarger, 1998), and in the Potomac River watershed near Washington, DC (various point and nonpoint discharges; Pinkney et al., 2001), and killifish in the Elizabeth River, Virginia (a wood treatment plant using creosote; Vogelbein et al., 1990). As stated earlier, PAHs appear to comprise a class of contaminant generally increasing in the environment. The metabolism of PAHs such as BaP to reactive metabolites that form DNA adducts that initiates carcinogenesis, or conversely to excretable conjugates, has been described earlier. It is noteworthy that the molecular and biochemical pathways underlying chemical carcinogenesis, such as PAH metabolism, DNA damage, and effects on oncogenes, are qualitatively similar between most fish and mammalian species examined.

This recognition of shared pathways has in part contributed to the use of various fish models for studying chemical carcinogenesis from a human health as well as from a broader environmental standpoint. An important historical event was the identification in Italy, France, and the United States during the 1950s and 1960s of aflatoxin as a potent liver carcinogen in farm-raised rainbow trout (Sinnhuber et al., 1977). Subsequently aflatoxin, a fungal toxin produced by *Aspergillus flavus* that is of concern where grains and nuts are stored in wet conditions, was found to be carcinogenic to mammals including humans. Thus, the rainbow trout observations led to the discovery of a new and important class of chemical carcinogens, and the recognition that fish can be very sensitive to chemical carcinogenesis. Since that time, other fish species have been employed for laboratory studies related to chemical carcinogenesis, particularly medaka (*O. latipes*) and platyfish/swordtails hybrids (*Xiphophorus* spp.); zebrafish also show promise as a laboratory model (Ostrander and Rotchell, 2005). Compared with rodent models, fish models have advantages of reduced costs for propagation and housing, briefer time intervals between exposures and the expression of tissue changes indicative of carcinogenesis, and greater feasibility of performing large-scale studies with many animals to quantify dose–response relationships.

It is noteworthy that the great bulk of reports of elevated cancer rates in free-living animals occur in fish, with few reports of potentially chemically related cancers to our knowledge in other vertebrates. California sea lions (*Zalophus californianus*) stranded along the central California coast were found to have elevated cancer rates (18%), and concentrations of DDT and PCBs were greater in animals with cancer versus those determined to die of other causes (Ylitalo et al., 2005). Martineau et al. (2002) reported elevated cancer rates (also 18%) in carcasses of beluga whales (*Delphinapterus leucas*) stranded along the shores of the St. Lawrence River estuary in Quebec, a system with elevated levels of PAHs. The authors noted that beluga was the only species of marine mammal among 20 inhabiting this system that exhibited elevated cancer rates, and that cancers are rare worldwide in marine mammals. It is likely that elevated exposures play an important role in the relatively high frequency of reports of cancers in benthic fish; relative inherent sensitivities among mammals, birds, reptiles, amphibians, and fish are unclear.

Population

A population is a collection of individuals of the same species that occupy the same space and within which genetic information can be exchanged. The study of populations is a central theme in ecological sciences and ecotoxicology is no exception. Assessment of toxicant effects on populations has been important in ecotoxicology

since its inception (Newman, 2001). A well-known, early instance is the sharp drop and then slow recovery of coastal populations of osprey (Spitzer et al., 1978) and brown pelican (Anderson et al., 1975) that occurred as a consequence of widespread DDT and DDE spraying and eventual banning. More recently, populations of Asian vultures scavenging on dead cattle dropped severely due to fatal poisoning by the veterinary drug diclofenac (Oaks et al., 2004; Balmford, 2013). Another was the enhanced, genetically based tolerance of pest insect populations chronically sprayed with pesticides (Mallet, 1989). Industrial melanism, the premier example in biology textbooks of natural selection in populations, is another example of population ecotoxicology. Populations of the peppered moth (*Biston betularia*) in industrial regions shifted from a predominance of light colored to melanic individuals as surfaces became progressively darkened due to soot deposition. Predation by visual hunters, especially birds, had exerted strong selective pressure on a single gene locus coding for coloration (Grant, 2004; Van't Hof et al., 2011).

Population ecotoxicology covers a wide range of topics with core research themes being (1) epidemiology of chemical-related disease, (2) effects on general population qualities including demographics and persistence, and (3) population genetics.

The level of belief warranted for possible contaminant-related effects in nonhuman populations is assessed by applying routine epidemiological methods. Many methods described in epidemiology textbooks (Anders, 1993; Woodward, 2005) are applied to nonhuman populations although with a slightly different balance because much more experimental exposure data are potentially available for nonhuman populations than for human populations. Rules of thumb for gauging the level of belief warranted by evidence that emerged from human epidemiology are also applied in population ecotoxicology. Hill's nine aspects of human disease association (Hill, 1965; see Chap. 2, "Principles of Toxicology") might be used directly or after minor modification. As an example, Fox (1991) (Table 30-1) modified such rules of thumb to accommodate slight differences in the subject matter and approaches in population ecotoxicology. Conventional epidemiological descriptors and models are also applied. For example, Horness et al. (1998) quantified prevalence and relative risks for neoplastic liver lesions in English sole from areas with different sediment concentrations of PAHs. Logistic regression models were also used to identify relationships between these lesions and chemical and biological risk factors (Myers et al., 1994).

Defining and predicting alterations in population size, dynamics, and demographic composition due to toxicant exposure have always been central in ecotoxicology and have become increasingly so in the last 20 years as regulatory agencies such as the U.S. Environmental Protection Agency clearly reinforced their long-standing commitment to understanding chemical exposure effects on natural population viability.

> *Protecting populations is an explicitly stated goal of several Congressional and Agency mandates and regulations. Thus it is important that ecological risk assessment guidelines focus upon protection and management at the population, community, and ecosystem levels . . . .*
>
> Environmental Protection Agency (1991)

Ecological theory and research (e.g., Forbes and Calow, 1999) also indicate that metrics of effect to individuals are not especially reliable metrics of toxicant exposure effects to populations.

Models of exposed population dynamics suggest that reductions on population densities are not the only important changes brought about by chemical exposure. Some species populations fluctuate within a range of densities. These fluctuations are characteristic of the species strategy for maintaining itself in various types of habitats and toxicant exposure could potentially change this range (Simkiss et al., 1993). Combined with decreases in population densities driven by external forces such as weather events, these toxicant-induced modifications of the average population densities and dynamics can increase the risk of a population's density falling so low that local extinction occurs (Newman, 1995).

Demographic qualities can change with toxicant exposure in ways that influence the risk of local population extinction. Toxicants can change a species population's vital rates, that is, age- and sex-dependent death, birth, maturation, and migration rates, in complex ways. These changes in combination determine the population density and distribution of individuals among ages and sexes during exposure. The population's ability to resist external forces that reduce its size is determined by these demographic features (Gard,

Table 30-1

A Summary of One Popular Set of Rules of Thumb (Data from Fox [1991]) for Assessing Plausibility of a Causal Association in an Ecological Epidemiology

RULE	DESCRIPTION
1. Strength of association	How strong the association is between the possible cause and the effect, for example, a very large relative risk
2. Consistency of association	How consistently is there an association between the possible cause and the effect, for example, consistent among several studies with different circumstances
3. Predictive performance	How good is the prediction of effect made from the presence/level of the possible cause
4. Monotonic trend	How consistent is the association between possible cause and effect to a monotonic trend (i.e., either a consistent increase or decrease in effect level/prevalence with an increase in exposure)
5. Inconsistent temporal sequence	The effect, or elevated level of effect, occurs before exposure to the hypothesized cause
6. Factual implausibility	The hypothesized association is implausible given existing knowledge
7. Inconsistency with replication	Very poor reproducibility of association during repeated field assessments encompassing different circumstances or repeated formal laboratory testing

NOTE : According to Fox (1991), the first four rules are most useful in supporting a causal hypothesis if found to be true (i.e., very strong, consistent, predictive, or monotonic association). The others are most useful for lessening belief in the causal hypothesis if true.

1992; Sherratt et al., 1999; Kammenga and Laskowski, 2000; Aubone, 2004). Consequently, considerable research effort is being spent on demographic methods for predicting exposed population changes and risks of extinction.

Demography explores vital rates of populations composed of individuals that differ in age and sex. Individuals in field populations can also differ in their spatial distribution and this influences the impact of toxicants (Newman, 2001). Individuals of the same species often are grouped into subpopulations within a habitat and all of these subpopulations together comprise a metapopulation (Fig. 30-9). Subpopulations in the metapopulation have different levels of exchange and different vital rates that depend on the nature of their habitat. Spatial distances and obstacles or corridors for migration influence migration among patches; habitat quality determines vital rates. An inferior habitat, such as a grossly contaminated one, can act as a sink into which individuals migrate from nearby superior (source) habitat. Migration can rescue a subpopulation or reduce its risk of local extinction. An individual migrating from the contaminated habitat to an uncontaminated one can express an adverse effect despite its present distance from the contamination, that is, the action-at-distance hypothesis of ecotoxicology (Spromberg et al., 1998). The viability of the metapopulation can also be as strongly influenced by maintaining important migration corridors among subpopulations and protecting high-quality habitats (i.e., keystone habitats) as by the general level of contamination within the metapopulation's habitat (Mauer and Holt, 1996; O'Connor, 1996; Spromberg et al., 1998; Newman, 2001).

The genetics of exposed populations is studied to understand changes in tolerance to toxicants and to document toxicant influence on field populations. The capacity of some populations to become more tolerant of toxicants via selection is well documented. A few examples include increased tolerance of pine mice to endrin (Webb and Horsfall, 1967) and rats to warfarin (Partridge, 1979) after years of application of these chemicals for rodent control. More recently, Ownby et al. (2002) documented enhanced tolerance in populations of an estuarine fish chronically exposed to PAHs. Although genetically based increases in tolerance are well documented in wild populations, many exposed populations probably find themselves in situations in which they cannot adapt adequately because their genetic resources, nature of the toxicant, or spatial/temporal context within which the enhanced tolerance must evolve are inadequate. Also, in an ecotoxicological sense, all cases of increased tolerance do not fit the conventional context manifested in the examples just given. Some do not involve suborganismal changes to biochemical or anatomical features resulting in enhanced tolerance. For example, industrial melanism increases a peppered moth's fitness in the presence of soot by reducing its likelihood of being taken by a predator. The dominant light form of this moth has a lowered fitness in the presence of dark soot, and genetically based changes in color increase its fitness. The selective mechanism here is ecological, that is, fitness relative to avoiding visual predators.

Genetic qualities are also used to infer past toxicant influence in an exposed population. For example, Mulvey et al. (2002, 2003) showed distinct genetic qualities in estuarine fish populations exposed to high concentrations of PAHs. Another piece of evidence demonstrating past toxicant influence on populations can be a change in genetic diversity. A drop in genetic diversity in populations is thought to be an adverse effect because genetic diversity is required in populations to evolutionarily adapt to environmental changes. Toxicants can influence genetic diversity by purely stochastic means. Genes can be lost in the population if the population is so drastically reduced in size that the chance of a rare gene being lost between generations becomes very high. Also, the average rate at which the frequency of a rare gene decreases through time due to genetic drift increases as the effective population size decreases. The effective population is the number of individuals contributing genes to the next generation so toxicant-related changes in demographic qualities can also accelerate genetic drift.

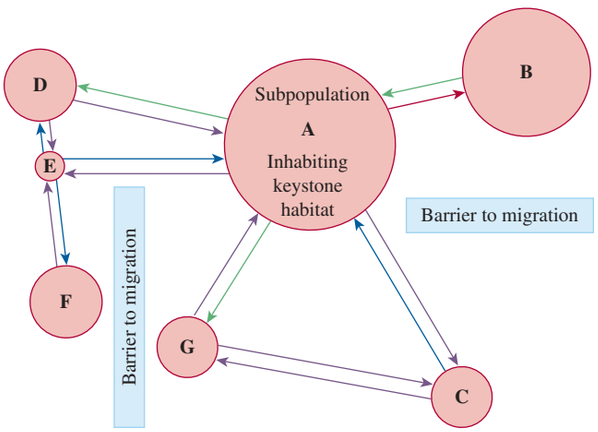

Figure 30-9. *Metapopulations are composed of subpopulations that differ in their vital rates and tendency to exchange individuals.* In this illustration, subpopulation A occupies a keystone habitat. The loss of subpopulation A would devastate the metapopulation. Also, loss of the migration corridor between subpopulations A, B, and D would devastate the metapopulation. In contrast, the loss of subpopulation F would not influence the metapopulation to the same degree.

Community

An ecological community is an interacting assemblage of species populations occupying a defined habitat at a particular time. Populations in a community interact in many ways and, because these many interactions are complex, a community has properties that are not predictable from those of its component populations. Some species have such a crucial role (keystone species) or numerical dominance (dominants) that they are essential to maintaining community structure.[2] Other species contribute to the nature of the community in more subtle ways. Community qualities like the diversity of species are influenced by contaminants. These effects are of concern because a decrease in diversity can diminish a community's ability to retain vital nutrients or resist stress such as that associated with drought (Tilman et al., 2006).

Ambiguity exists about the importance of all the species in a community relative to maintaining overall structure and balancing essential functions such as nutrient cycling, primary productivity, community respiration, and detritus processing. The redundant species hypothesis suggests that species function redundantly: if a species were lost, another with a similar function would increase in numbers to compensate. Only certain critical species such as dominant or keystone species are essential to the community. The rivet popper hypothesis suggests otherwise. Each species in a community is similar to one of the many rivets holding an airplane

[2]In its most rudimentary context, community structure refers to the number of species present and the number of individuals present in each of these species. It can also refer to the distribution of species among different functional groups such as decomposers, detritivores, primary producers, primary consumers such as herbivores, and secondary consumers such as carnivores that consume herbivores.

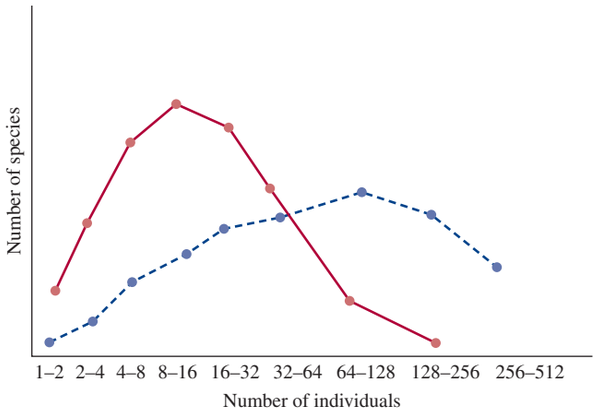

Figure 30-10. *Log-normal model of species abundance for an unexposed (solid line and red points) and toxicant-exposed community (dashed line and blue points).* Communities have distinct structure as shown here with the typical log-normal species abundance model. As first described by data from Patrick (1973), ecotoxicants tend to lower the mode of the species abundance curve and stretch the right tail outward. Ecotoxicants result in fewer intermediate abundance species and more extremely abundant species.

fuselage together. Each lost rivet contributes to a gradual weakening of the fuselage that will lead eventually to a failure in function. By analogy, each species disappearance diminishes a community's functioning.

Ecotoxicologists remain divided about which hypothesis is most relevant. Pratt and Cairns (1996) argue from evidence and a conservative stance that the rivet popper is the most appropriate. Ecotoxicologists and regulators who pragmatically set standards based on concentrations that will not harm more than a specified percentage of species in a community (e.g., Stephan et al., 1985) assume that the redundant species hypothesis is more pertinent. Although the redundant species hypothesis is assumed to be correct in many ERAs (Solomon and Sibley, 2002), recent theory (Loreau, 2004), modeling (Naeem et al., 1994), and experimental evidence (Tilman, 1996; Tilman et al., 1996; Salminen et al., 2001) seem to support the rivet popper hypothesis. Biodiversity tends to foster community stability and function.

Communities take on characteristic structures as predicted by the Law of Frequencies: the number of individual organisms in a community is related by some function to the number of species in the community (Fig. 30-10). Ecotoxicants[3] can alter the resulting community structure in predictable ways by either directly impacting the fitness of individuals in populations that make up the community or altering population interactions. Community ecotoxicologists spend considerable effort trying to understand and predict ecotoxicant influences on community structure and essential functions.

Direct effects involve removal of a population or metapopulation from the community by reducing the Darwinian fitness of individuals enough that the population falls below some critical minimum size. Indirect effects can involve interference with interspecies competition, predator–prey interactions, host–disease/parasite interactions, or symbiotic relationships such as pollination. The simplest competition model (Lotka–Volterra model) can be used to illustrate the potential for both direct and indirect effects on populations:

$$\frac{dN_1}{dt} = r_1 N_1 \left[1 - \frac{N_1}{K_1} - \frac{\alpha_{12} N_2}{K_1}\right],$$

$$\frac{dN_2}{dt} = r_2 N_2 \left[1 - \frac{N_2}{K_2} - \frac{\alpha_{21} N_1}{K_2}\right],$$

where N_1 and N_2 are the population sizes of competitors 1 and 2, K_1 and K_2 the carrying capacities of the environment for competitors 1 and 2, r_1 and r_2 the intrinsic rate of population increase (i.e., birth rate − death rate) for competitors 1 and 2, α_{12} the competition coefficient quantifying the impact of the presence of competitor 2 on competitor 1, and α_{21} the impact of competitor 1 on competitor 2. Not only can exposure directly impact birth rates, death rates, and carrying capacity of each species, but it can also influence species persistence by shifting competition coefficients in favor of another species. Mathematically, it can be shown that the two competitors depicted in the Lotka–Volterra model can coexist only if two conditions are met, $K_1 < K_2/\alpha_{21}$ and $K_2 < K_1/\alpha_{12}$. So, a population can be lost from a community as readily by changing its competitive interactions as by directly changing its death and reproductive rates. Similar statements can be made about changes in predator–prey, host–disease, and various symbiotic interactions. As an example, concern expressed recently about unintended pesticide reductions in the number and diversity of pollinators in European farmlands (Newman et al., 2006) could be partially responsible for the recently reported decline in insect-pollinated plant species in Britain and the Netherlands (Biesmeijer et al., 2006). In another instance, reduced habitat cover and insect densities in European farmlands has had a significant impact on gray partridge populations (Rands, 1985; Chiverton, 1999). As another and final example involving predator–prey interactions, amphibian tadpole exposure to endosulfan, a chlorinated insecticide, increases the risk of predation by dragonfly larvae (Broomhall, 2002). None of these examples involves a direct poisoning by a toxicant, but instead, involves an ecotoxicant that adversely modifies species interactions.

Structural changes to communities can be detected in species abundance plots (see Fig. 30-10) or shifts in conventional community metrics calculated from community samples taken in the proximity of contaminated sites. Common metrics for species richness, diversity, and evenness are used to express changes in biodiversity. Richness is simply the number of species in the sampled community, or if a relative number of species in different communities is all that is needed, the number of species expected in a specified sample size such as a rarefaction richness estimate of 12 species in a sample of 100 individuals from a community. Evenness is a measure of how equitably the individuals in a community are spread among the species. Finally, diversity (heterogeneity) indices combine the elements of richness and evenness into one number. Generally, but not always, ecotoxicants lower species richness, evenness, and overall diversity. The regulatory premise is that these changes reflect a diminished community.

Structural and functional qualities in communities have been combined to generate multimetric indices such as the Index of Biotic Integrity (IBI) (Karr, 1991). Ecological insight is used to select and then numerically combine community qualities such as species richness, health of individual animals in a sample, and the

[3]The conventional context for the term "toxicant" becomes difficult to retain without some qualification when dealing with populations, communities, and other higher level entities because an agent does not necessarily have to directly interact with the individual in order to harm it. As an example, an agent might eliminate a prey species, leading indirectly to the disappearance of a predator species that depended on it for sustenance. The "toxicant" did not poison the predator, yet it caused its demise nonetheless. A distinct term "ecotoxicant" is often applied to avoid confusion in such cases.

number of individuals in a sample belonging to a particular functional group, such as number of piscivorous fish. The IBI score for a study site is calculated and compared with that expected for an unimpacted site in order to estimate its biological integrity.

Another central theme in community ecotoxicology is toxicant transfer during trophic interactions. Toxicant concentrations can decrease (biodiminution), remain constant, or increase (biomagnification) with each trophic transfer within a food web. Persistent organic pollutants (POPs) with moderately high lipid solubility ($5 < \log K_{ow} < 7$ or 8; Thomann, 1989; Connell, 1990) and minimal metabolic breakdown in an organism can biomagnify to harmful concentrations. Metals that biomagnify are mercury and the alkali metals, cesium and rubidium. Zinc, an essential metal that is actively regulated in individuals, can exhibit biomagnification or biominification depending on whether ambient levels are below or above those required by the organism to function properly. Biominification is facilitated in a marine food web after sequestration in intracellular phosphate granules of molluscan prey species (Nott and Nicolaidou, 1993) and biomagnification by active regulation in zinc-deficient terrestrial communities (Beyer, 1986). The biomagnification of mercury is enhanced by its microbial transformation to methylmercury. Biomagnification of the potassium analogs, cesium and rubidium, is facilitated by the differences in their influxes and effluxes that favor retention in organisms (Rowan and Rasmussen, 1994; Campbell et al., 2005).

Quantifying the trophic position of a species in a community is essential to modeling biomagnification. Most trophic systems are not simple "food chains." Most individuals in a community can feed on different species depending on their life stage, seasons, and relative abundances of prey species. These trophic interactions are best described as occurring in a trophic web, not a trophic chain.

Conveniently, trophic position of an individual within a complex food web can be quantified with nitrogen isotopes. Generally, ^{14}N passes through biochemical pathways faster than ^{15}N, resulting in excretion of waste with a slightly higher $^{14}N/^{15}N$ ratio than in ingested food. The relative amounts of ^{14}N and ^{15}N will be slightly biased toward the heavy isotope in tissues of a species relative to those of its food source(s). This discrimination between the heavy and light N isotopes continues through food webs, allowing the trophic position of each participating species to be estimated. The metric used for this purpose, the $\delta^{15}N$, expresses the quotient of these two isotopes in the biological tissue of interest relative to the quotient expected in the atmosphere:

$$\delta^{15}\mathrm{N}=1000\left[\frac{\left[{}^{15}\mathrm{N}_{\mathrm{Tissue}}\right]/\left[{}^{14}\mathrm{N}_{\mathrm{Tissue}}\right]}{\left[{}^{15}\mathrm{N}_{\mathrm{Air}}\right]/\left[{}^{14}\mathrm{N}_{\mathrm{Air}}\right]}-1\right].$$

The change in toxicant concentrations within food webs is modeled using the $\delta^{15}N$, which quantifies trophic position of the species from which the tissue sample was taken (Fig. 30-11). Linear and exponential models are commonly applied:

$$\text{Concentration} = a + b\delta^{15}\mathrm{N},$$

$$\text{Concentration} = 10^{a+b\delta^{15}\mathrm{N}} \text{ or } e^{a+b\delta^{15}\mathrm{N}}.$$

Ecosystem to Biosphere

Ecosystems are the functional unit of ecology composed of the ecological community and its abiotic habitat. Systems ecologists try to describe and predict energy and mass cycling in and flow from ecosystems. The ecotoxicologist's interest in ecosystems includes understanding how toxicants diminish an ecosystem's capacity to perform essential functions and to understand toxicant movement enough to assess exposure within different ecosystem components.

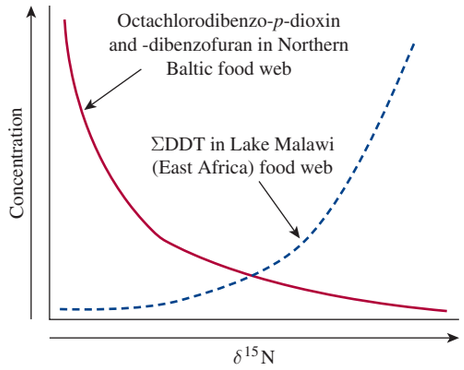

Figure 30-11. *Modeling ecotoxicant concentration versus trophic position as quantified with $\delta^{15}N$.* Power models were applied to octachlorodibenzo-*p*-dioxin/dibenzofuran concentrations in a North Baltic food chain (data from Broman et al. [1992]) and the ΣDDT (sum of primarily the *p,p′* isomers of DDD, DDE, and DDT) in food webs of Lake Malawi (data from Kidd et al. [2001]). Biomagnification and minification were evident for ΣDDT and octachlorodibenzo-*p*-dioxin/dibenzofuran, respectively.

Many of the effects described above for exposed communities are relevant here. As an example, Allred and Giesy (1988) demonstrated that elevating cadmium concentrations in an artificial stream reduced decomposition rates of dead leaves. Odum (1985) suggested that other changes to be expected with increased ecosystem stress include an increased loss of nutrients, increased community respiration, and an imbalance of primary production and respiration.

Studies of toxicant movement within ecological systems are conducted at extremely different scales (Fig. 30-12). Conventional ecosystem studies involve descriptions of contaminant concentrations and movements in easily defined ecosystems such as lakes, forests, or fields. Some toxicants, especially those subject to wide dispersal by air or water, cannot be completely understood in this framework so a landscape scale might be chosen instead. As an example, acid precipitation might be examined in the context of an entire watershed, mountain range, or even a continental region. As another example (see Fig. 30-12, top right panel), the fish tissue concentrations of a PCB congener and other persistent organic pollutants (POPs) were measured in high mountain region lakes of Europe. Concentrations for several were related to the altitude at which a lake sat. Called mountain cold-trapping, the relationship between altitude and concentrations of the various POPs is determined by atmospheric movement of the POPs and each POP's propensity to either volatilize or condense at a particular altitude-dependent temperature regime (Blais et al, 2003; Wania and Westgate, 2008; Westgate and Wania, 2013). Still other ecotoxicants require a global context to fully understand their movements and accumulation. As an example, hexachlorobenzene concentration in tree bark collected worldwide showed a clear latitudinal gradient. Its global distribution and those of other sampled POPs were a function of their relative volatilities. The volatile hexachlorobenzene moved more readily toward the poles than less volatile POPs such as endosulfan and DDT. The differential global movement of POPs due to differences in volatility and partitioning behavior was called global distillation and fractionation (Simonich and Hites, 1995; Wania and Mackay, 1996). The balance between a POP's tendency to condense or evaporate at different latitude-related temperatures

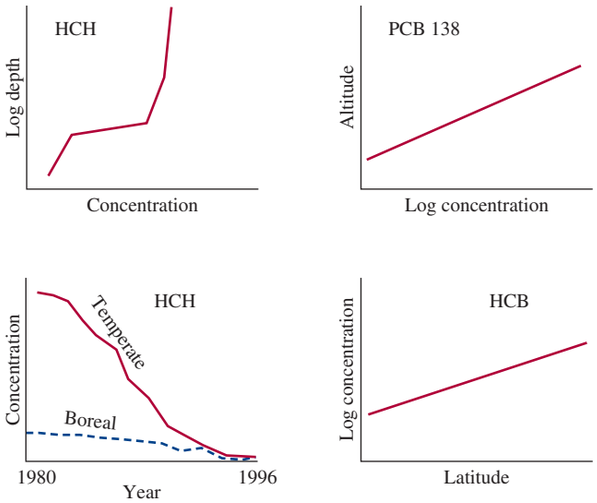

Figure 30-12. *Examples of scales relevant to assessments of ecotoxicant distributions.* The smallest scale example (*top left*) is the vertical distribution of α-hexachlorocyclohexane (HCH) in a stratified region of the Sea of Japan (data from Chernyak et al. [1995]). A slightly larger scale is reflected in the change in the polychlorinated biphenyl congener PCB 138 in tissues of fish inhabiting European lakes at different altitudes. (*Top right panel*, data from Fernandez and Grimait [2003].) Representing a subcontinental scale study is the temporal change in atmospheric α-hexachlorocyclohexane concentrations in temperate and boreal regions of central northern Europe. (*Bottom left panel*, data from Wania et al. [1999].) The largest scale encompasses the entire Earth, showing the influence of latitude on hexachlorobenzene (HCB) concentration in tree bark. (*Bottom right panel*, data from Simonich and Hites [1995].)

determines its atmospheric mobility and its ultimate global deposition pattern (Wania and Mackay, 1996).

APPROACHES

Many approaches have been developed to detect and quantify contaminant effects. These span the levels of organization described above. Approaches widely applied in ecotoxicology include standardized toxicity tests deigned to meet regulatory needs and biomarkers for organismal exposure and effects. For higher levels, a range of ecological methods exists for population, community, and ecosystem effects. Other techniques such as geographic information system (GIS) analysis of impacts allow the ecotoxicologist to assess impact encompassing large spatial scales. These approaches and examples of their applications are described in this section.

Toxicity Tests

Toxicity testing encompassing representative animals and plants at different levels of organization offers a practical approach to characterize chemical effects on biological systems. While it is widely known that toxicity tests cannot mimic the complex interactions and variable conditions of natural ecosystems, they address the potential direct effects of toxic substances on individual ecosystem components in a controlled and reproducible manner. A number of testing guidelines have been put forth by regulatory bodies and organizations worldwide to meet requirements for chemical registration or authorization (OECD, 1981; MAFF, 1985; U.S. EPA OPPTS, 1996a; ASTM International, 2006), with numerous subsequent revisions. Different sets of guidelines apply to specific countries, regions, or products, and can differ significantly in their requirements. The harmonized guidelines put forth by the U.S. EPA Office of Prevention, Pesticides and Toxic Substances (U.S. EPA OPPTS, 1996a) were created in an attempt to lessen variations in testing requirements, and bring together requirements from the Organisation for Economic Co-Operation and Development (OECD), the U.S. EPA Office of Pollution Prevention and Toxics (OPPT), and the Office of Pesticide Programs (OPP).

Ecotoxicology tests feature a wide variety of aquatic (including algae, invertebrates, tadpoles, bivalves, shrimp, fish), avian (quail, duck), and terrestrial species (soil microorganisms, crops, honey bees, earthworms, wild mammals). Species are selected based not only on their traditional use as laboratory animals, but also on ecological relevance, which further complicates global harmonization of ecological testing. In addition, special considerations apply to testing of aquatic species due to the unmistakable differences in the way aquatic species are exposed to toxicants (U.S. EPA OPPTS, 1996b). For instance, water quality monitoring and investigation of the solubility and stability of the test substance under the conditions of testing, along with determination of nominal versus measured concentrations, are common practices in aquatic toxicology. Testing can be conducted in aqueous systems without renewal of the test substance (static), renewal at predetermined time intervals (static renewal), or continuous flow of test substance through the test compartment (flow-through).

Acute toxicity testing consists of single species exposed to various concentrations of the test substance. The most common endpoint in acute tests is death, although abnormal behavioral or other gross observations are commonly noted, and nonlethal endpoints occasionally apply (e.g., immobilization for daphnids and shell deposition in oysters). Variations in acute toxicity studies comprise testing of different species (such as fresh vs. saltwater fish, bobwhite quail vs. mallard duck), life stages (embryo, larva, juvenile), environmental influences (e.g., presence of organic material), or sediment exposures. Data from various test concentrations and time points are used to derive concentration–response curves and predicted values such as the LC_{50} (median lethal concentration), EC_{50} (median effective concentration), or IC_{50} (median inhibition concentration). The LC_{50} represents the concentration of test substance killing 50% of the tested animals and EC_{50} the concentration of test substance affecting 50% of the test population during a specified period of time, such as growth; the IC_{50} is the concentration causing a 50% reduction in a nonquantal measurement (such as movement) for the test population. More quantitative values derived from acute tests are the lowest observed effect concentration (LOEC), that is, the lowest concentration where an effect is observed, and the no observed effect concentration (NOEC), the highest concentration resulting in no adverse effects.

Short-term laboratory studies conducted with single species are useful for rapid screening, provide information on thresholds for effects and selective and comparative toxicity, and can be used as range finders to guide subsequent, often more involved studies. Long-term and reproductive studies evaluate the effects of substances on organisms over extended periods of time and/or sequential generations (chronic toxicity, life cycle, reproduction). Endpoints include both quantal (such as mortality) and nonquantal (reproduction, growth) measurements, and can be used to derive additional values, other than previously mentioned in acute toxicity tests. These include the calculation of threshold values, such as the maximum acceptable toxicant concentration (MATC), which is the maximum chemical concentration not toxic to test organisms, and the BCF, which estimates the tissue concentration in relation to the average exposure concentration in the test medium (e.g., water).

Unique to ecotoxicology are the more elaborate microcosm, mesocosm, and field studies. Microcosms are representative aquatic

or terrestrial ecosystems created under laboratory conditions that include a number of relevant species (such as protozoa, plankton, algae, plants, and invertebrates). Simulated field studies or mesocosms can be created in the laboratory or in the field (e.g., artificial streams, ponds) or consist of enclosures of existing habitats, containing representative soil, water, and biota. Lastly, full-scale field studies (aquatic organisms, terrestrial wildlife, pollinators) evaluate the effects of a substance on wildlife under real-life scenarios of actual use conditions of a product (e.g., pesticide field usage rate), and thus, are more complicated, subject to considerable variability, and require extensive background knowledge of the local population and community dynamics.

As a final point, plant studies are a significant component of ecological toxicity testing, particularly for pesticide registration, and involve tiered testing of both target area and nontarget terrestrial and aquatic plants. Target area plants are those that are present in the area where the substance will be routinely used (application area), but which are not anticipated to be affected. Nontarget plants are those outside of the intended use area. Endpoints of phytotoxicity include seedling emergence and growth, vegetative vigor, and rhizobium–legume toxicity, among others, and central to the toxicity testing with plants are the substrate and environmental conditions, which greatly influence plant health.

Biomarkers

The Nuclear Regulatory Commission (NRC, 1989) defined a biomarker as "a xenobiotically induced variation in cellular or biochemical components or processes, structures, or function that is measurable in a biological system or sample." In the context of ecotoxicology, this definition has been modified slightly to refer to biochemical, physiological, or histological indicators of either exposure to or effects of xenobiotic chemicals at the suborganismal or organismal level (Huggett et al., 1992). The term is most often employed to refer to molecular, physiological, and organismal responses to contaminant exposure that can be quantified in organisms inhabiting or captured from natural systems. A response that is limited to laboratory studies falls outside the generally held concept of a biomarker.

By definition, biomarkers do not directly provide information concerning impacts on the higher levels of organization that ecotoxicology ultimately endeavors to discern. Nevertheless, biomarkers often provide important ancillary tools for discerning contaminant exposures and potential impacts of ecological importance. The development and use of biomarkers in ecotoxicology is motivated by several factors. These include the inherent instabilities of many contaminants (such as PAHs and many pesticides) that make measures of exposure by direct tissue residue analysis difficult, the relative biological sensitivity of many biomarkers, the chemical specificity of some biomarkers that serve to contribute to the identification of chemicals having biological effects, and relatedly, the linkage of some biomarkers to underlying mechanisms of toxic action. Additionally, while populations and higher level effects are of greatest concern, variables associated with these levels are oftentimes relatively insensitive to chemicals and other stressors, take long periods of time to become manifest, and/or have difficult or imprecise methods for their analysis. Thus, biomarkers can provide sensitive early warning signals of incipient ecological damage (van der Oost et al., 2003), in essence an ecological counterpart to the "canary in the coal mine" approach for preventing harm to coal miners. However, biomarkers do not provide adequate stand-alone data in the context of ecological assessments of contaminant effects. At this time and for the foreseeable future, such assessments generally involve a "weight of evidence approach," coalescing information obtained from chemical analyses, toxicity tests, biomarkers, and ecological indicators (sometimes referred to as "bioindicators"; see Adams et al., 1989). The AOP concept described earlier provides a more formal approach for linking data across levels of organization.

In earlier discussions, a number of contaminant effects at the organismal level and below that have been utilized as biomarkers were pointed out. These include effects with some degree of chemical specificity and relationship to a mechanism of toxicity (AChE inhibition by organophosphate and carbamate insecticides, ALAD inhibition by lead, DNA–PAH adducts), responses associated with exposures to chemicals acting through a common receptor (Vtg induction by ER agonists such as natural and synthetic estrogens, some surfactants, plasticizers, and pesticides; CYP1A induction by AhR agonists such as certain pHAHs and PAHs), and broader indices of cellular stress or tissue damage, such as markers of oxidative stress, lysosomal membrane stability, and histopathology. Numerous other identified mechanisms of toxicity, indices of chemical exposure, and cellular and organismal impacts have been exploited, with varying degree of success, as biomarkers (see reviews by Huggett et al., 1992; Peakall, 1992; Adams, 2000; van der Oost et al., 2003; Connon et al., 2012). In addition, new biomarkers continue to emerge; for example, considerable attention is now being given to biomarkers arising from advances in genomic technologies, discussed in Section "Genomics and Ecotoxicogenomics."

In considering the development or use of a selected biomarker, several issues and limitations warrant consideration. For example, while sensitivity is overall an advantage of many biomarkers, it can sometimes raise important questions surrounding interpretation. For example, some molecular and biochemical measures are very sensitive to chemical exposures, but their ramifications for organismal health are unclear. For this reason, some distinguish between biomarkers of exposure and biomarkers of effect (see reviews cited earlier in this chapter). However, this distinction is often blurred and is subject to an individual's view of what constitutes a significant biological chemical effect; some may say the formation of DNA adduct is a significant effect, while others will argue that such adducts only indicate exposure and will require tumor formation to occur before denoting an effect. Certainly most would agree that the tumor is a clearer marker of effect than the adducts, and something more readily grasped by policy makers and the general public. On the other hand, tumors are far less sensitive as a biomarker, a key *raison d'etre*; such trade-offs merit consideration.

Chemical specificity among biomarkers is also highly variable and is imbued with trade-offs. In some cases, such as where one has a good idea of the nature of contaminants likely to occur at a site, chemical-specific biomarkers will likely be most informative. In contrast, if such information is lacking, or mixtures encompassing several classes of chemicals likely occur, nonspecific markers may be superior. In most cases, suites of biomarkers prove to be most effective, although the larger the suite, the more time-intensive and costly the analysis will be—another trade-off. Another important consideration is the influence on the biomarker of variables other than those of concern (chemical contamination). Effects of environmental variables such as temperature, time of day or year, salinity and dissolved oxygen, and physiological variables such as sex, age, reproductive status, and nutritional status need to be controlled for or at least understood and accounted for. Many biomarkers are invasive and require sacrifice of the organism in order to obtain needed tissues. This can be problematic, particularly in cases involving rare species or charismatic species such as marine mammals. In such cases, and in others where feasible, the use of noninvasive biomarkers is either preferred or required (Fossi and Marsili,

1997). In summary, biomarkers can provide powerful tools as early warning signals of ecological damage to assist in assessments of environmental contamination and in determining the effectiveness of various environmental management decisions such as cleanups. However, careful case-specific thought must go into the selection of biomarkers, and they rarely are efficacious alone.

Population

Population-level effects are quantified with both field and laboratory approaches (see Newman, 2001, 2013). Population density is the most common of field population qualities measured in surveys of contaminated habitats. Quadrat, mark-recapture, and removal-based methods are applied. The density of individuals in a series of random quadrats within the area of interest is used to estimate densities in quadrat methods. The total population size can be estimated with knowledge of the total number of quadrats in the area of interest. In cases in which individuals are mobile and capable of avoiding being counted in a quadrat, a mark-recapture method might be applied instead. This involves marking a subset of individuals from the population, allowing them to randomly mix back into the population, and resampling the population. The number of marked and unmarked individuals taken, and the total number originally marked, can be used to estimate population size. Removal-based methods involve repeated sampling of the population without replacement, noting how the number collected per unit of effort declines through the sequence of samplings, and extrapolating this trend down to the point (total number caught previous to a sampling) at which no more individuals will be taken. This point is an estimate of the population size. Obviously, this approach is useful only if sampling decreases the catch noticeably between sampling episodes.

As noted earlier in discussions of metapopulations, the spatial distribution of individuals in a habitat is important to understand. Fortunately, well-established methods are available for this task. Methods vary depending on whether the sampling units are discrete or arbitrary. An arbitrary unit might be the number of razor clams per square meter of beach or number of a zooplankton species per cubic meter of water. A discrete sampling unit might be the number of mallard ducks per pond or squirrels per oak tree. Some methods associated with discrete sampling units attempt to fit the spatial pattern to a specific distribution. Methods for arbitrary sampling units include quadrat-based or distance-to-nearest-neighbor approaches as described by Krebs (1998).

Demographic surveys or experiments can be conducted for exposed populations. Some studies explore age-specific vital rates but others are designed to explore vital rates for different life ages such as nestling, fledgling, juvenile, and adult. Most result in data sets that can be analyzed profitably using either a simple life table or more involved matrix analysis. The matrix method allows one to describe the population state and also to understand the sensitivity of the population to effects occurring to vital rates for various ages or stages (Caswell, 2001). The value of such studies lies in the ability to integrate effects to several effects into a projection of population consequences. Demographic studies are becoming more common in ecotoxicology, especially with species amenable to laboratory manipulation (Jansen et al., 2001; Tanaka and Nakanishi, 2001; Chandler et al., 2004).

Conventional studies of increased tolerance after generations of exposure and molecular genetic surveys of exposed populations are the primary approaches by which genetic consequences are assessed. Increased tolerance is usually detected by subjecting individuals from the chronically exposed population and a naive population to toxicant challenge and formally testing for tolerance differences. A recent example is the study by Ownby et al. (2002) of enhanced tolerance for a PAH-exposed population of killifish from Elizabeth River (Virginia). Alternatively, a change associated with a tolerance mechanism might be examined in chronically exposed and naive populations. As an example, Meyer et al. (2003) found upregulated antioxidant defenses in the same populations of exposed Elizabeth River killifish studied by Ownby et al. (2002). Close examinations of population genetics associated with contaminated habitats are also used to infer consequences of multigenerational exposure. Continuing with the Elizabeth River killifish example, Mulvey et al. (2002, 2003) examined the genetic qualities of fish sampled within the Elizabeth River estuary using allozymes and mDNA. Clear evidence was found using both tools for the influence of contamination on the population genetics of killifish subpopulations within the estuary.

Community and Ecosystem

Most community and ecosystem effects studies by ecotoxicologists use modified methods developed in community and systems ecology (see Magurran [1988] for method descriptions). Recent books, for example, by Newman (2015) and Newman and Clements (2008) provide some details of ecotoxicological applications of these methods. Several general approaches are taken. The approach affording the most control and ability to replicate treatments involves laboratory microcosms. A microcosm is a simplified system that is thought to possess the community or ecosystem qualities of interest. The experimental control and reproducibility associated with microcosms come at the cost of losing ecological realism. Is the laboratory microcosm actually responding in a way that provides insight about how the actual community or ecosystem would respond? Microcosm studies are so common throughout the ecotoxicological literature that standard methods have been proposed for their execution (Taub, 1997).

As a microcosm example, Clarke (1999) established invertebrate communities in the laboratory to determine the influence of oil drilling muds on offshore benthic communities. Relative to the issue of community redundancy discussed in the section "Community," zinc-amended soil microcosms were used in another case by Salminen et al. (2001) and provided minimal evidence to support the current reliance on the redundant species theory by ecological risk assessors.

Gaining back some realism by giving up some degree of tractability, outdoor mesocosms are also applied to community and ecosystem ecotoxicology. Mesocosms are larger experimental systems, usually constructed outdoors that also attempt to simulate some aspect of an ecosystem such as community species composition. Often, terrestrial ecotoxicologists apply the term enclosure instead of mesocosm for such experimental units. Aquatic mesocosms can be artificial ponds such as those developed by Woin (1998), streams such as those used by Kreutzweiser et al. (2000), or river segments such as those used by Culp et al. (2000). Terrestrial mesocosms can be pens, enclosures, or large soil plots depending on the effects being quantified. An example of a terrestrial mesocosm study is that conducted by Korthals et al. (1996) of the effects of long-term copper exposure to soil nematode communities. The Canadian Experimental Lakes program is a unique series of whole-lake studies in which lakes are dosed with various agents and whole ecosystem fate and effects studied. Agents studied in this manner include radionuclides, acid rain, cadmium, climate warming, mercury, 17α-ethynlestradiol, excess nutrients, and PCBs (Blanchfield et al., 2009; Schindler, 2009).

Field studies are the third means of exploring effects at the community or ecosystem level. The high realism of associated

findings from field studies is balanced against the difficulty of achieving true replication and sufficient control of other factors influencing the system's response. Field studies can involve manipulations such as introducing toxicant into replicate water bodies; however, the majority of field studies involve biomonitoring of an existing, notionally impacted, community or ecosystem. This might involve close examination of species composition and comparison to that expected or measured in a similar, but uncontaminated, system. Most biomonitoring efforts focus on community structure instead of function because it is generally thought that changes in community structure will be seen before those in functions. As examples, metal effects on invertebrate and plant community structure were studied by Peeters et al. (2000) and Strandberg et al. (2006), respectively. Despite the tendency to study community structure, study of functions can provide valuable insights as in the case of Day (1993), who found changes in photosynthesis in periphytic algae in response to herbicide exposure. Because mesocosm and field studies involve data generation in the presence of many uncontrolled variables and poor replication or pseudoreplication, multivariate statistical techniques for recognizing patterns among locations or through time are commonly applied (e.g., Landis et al., 1997; Kedwards et al., 1999).

Landscape to Biosphere

The creation and eventual convergence of several key technologies facilitate ecotoxicological study at the landscape to biosphere vantages. These same technologies have also allowed the emergence of large context, environmental disciplines such as landscape[4] ecology (Forman and Godron, 1986), global ecology (Rambler et al., 1989), and global biogeochemistry (Butcher et al., 1992) that contribute concepts to large-scale ecotoxicology efforts.

Technologies for acquiring, processing, and analyzing large amounts of information have been essential. Archived and new imageries from satellites and high-altitude platforms are now integrated with off-the-shelf geographic information system (GIS) software with affordable computers. Much of this imagery is gathered with remote sensing technologies, that is, technologies that do not require physical contact with the feature being measured. However, arrays of sensors are rapidly coming together such as the network coastal observing systems that are quickly linking to form a readily accessible real-time data stream for all of our oceans. Remote sensing data from satellites or aircraft provide information for wide spatial areas and the rapidly emerging, ground- or water-based observing system networks have begun to produce extremely rich data streams. Such technologies facilitate ecotoxicological explorations at spatial scales that were impossible to consider only a few decades ago.

ECOLOGICAL RISK ASSESSMENT

Ecological risk assessment (ERA) applies ecotoxicological knowledge in support of environmental decision making. The ERA approach is an adaptation of human risk assessment methods, notably those articulated in the National Academy of Sciences paradigm (National Research Council, 1983). Adaptations are needed to accommodate differences in exposure pathways and the entities for which risk is to be estimated. Risk might be to an endangered or threatened species, or to a damaged natural resource for which remuneration might be required from a responsible party. In such cases, the ERA might estimate risk to individuals. Alternatively, as emphasized in the above EPA quote, the risk might be to a local species population or to the integrity of an ecological community. A widely dispersed ecotoxicant such as acid precipitation or widely used product such as the herbicide, atrazine, might require assessment of risk at a landscape or subcontinental scale. A recent example of such a risk assessment is that for atrazine, a herbicide used throughout North America (Solomon et al., 1996). Ecotoxicants requiring a global ERA might include greenhouse gases contributing to global warming, hydrofluorocarbons depleting the ozone layer, and persistent organic pollutants (POPs) that accumulate to harmful concentrations in polar regions far from their point of release at highly industrialized latitudes.

Adaptations are based on the context of an ERA. Some ERAs address existing situations. Considerable field information might be available for such a retroactive ERA and epidemiological methods might be applied advantageously. In contrast, predictive ERAs assess possible risk associated with a future or proposed toxicant exposure. In this case, the ERA might rely more heavily on exposure modeling and laboratory-derived effects data. A special case of predictive risk assessment is a life cycle assessment in which "cradle-to-grave" predictions are done for a product that includes all aspects of its raw material extraction, manufacture, distribution, use, and final disposal. Finally, an ERA will be structured slightly differently if it compares the ecological risk of one or more options. An example would be the comparative risk associated with a spill of bunker oil versus Orimulsion® (a bitumen-based fossil fuel). Such a comparative risk assessment might draw insight and data from existing spill sites, laboratory tests, and exposure models. Despite adaptations and differing contexts, most ERAs have the same general form (see Fig. 30-2).

Risk assessors, risk managers, and key stakeholders engage in initial planning together with the intention of formulating a clear statement of the problem. What valued ecological entity or quality is being assessed (assessment endpoint) is defined. A conceptual model is created that links the assessment endpoint and the toxicant, including descriptions of exposure pathways and possible effects. A clear statement of possible or predicted effects (risk hypothesis) is formulated. A clear formulation of the problem with concurrence of key stakeholders is critical to the ERA because of the diversity of possible assessment endpoints and exposure pathways.

Exposure characterization describes or predicts contact between the toxicant and the assessment endpoint. Depending on the ERA context, this could involve a simple calculation of average exposure, or a temporally and spatially explicit description of amounts present in relevant media. Toxicant sources, transport pathways, kinds of contact, and potential costressors are also defined.

Ecological effects characterization describes the qualities of any potential effects of concern, describes the connection between the potential effects and the assessment endpoint, and describes how changes in the level of exposure might influence the effects manifesting in the assessment endpoint. Normally, a statement about the strength of evidence associated with the descriptions is presented in the ecological effects characterization. As a common example of evidentiary uncertainty often requiring explanation is the measurement endpoint. It is not always desirable to derive effects information directly from an assessment endpoint such as an endangered species so uncertainty is introduced by gauging effects to a surrogate (measurement endpoint). Ecological effects characterizations must describe the justifiable confidence in extrapolating

[4]A landscape is formally defined by Forman and Godron (1986) as a heterogeneous landscape that is "composed of a cluster of interacting ecosystems that is repeated in a similar form throughout." Each ecosystem is a part of a whole landscape much as a tessera is part of a mosaic or a subpopulation is part of a metapopulation.

from measurement to assessment endpoints. As discussed earlier, the AOP approach is gaining traction as a powerful approach for ecological (and human health) risk assessments, particularly for effects characterization.

Risk characterization uses the analysis of exposure and ecological effects to address the risk question(s) posed in the problem formulation. This can involve an explicit statement of risk, that is, the probability of a specified intensity of an adverse effect occurring to the assessment endpoint. Often, the information needed to make such an explicit statement is absent and a qualitative statement of the likelihood of an adverse effect is made instead. Regardless of whether a quantitative or qualitative statement of risk is produced, the risk characterization must provide details surrounding the statement, including important uncertainties.

INTERCONNECTIONS BETWEEN ECOSYSTEM INTEGRITY AND HUMAN HEALTH

As noted at the beginning of this chapter, while the original definition of ecotoxicology included effects on humans, most subsequent treatments exclude discussions of humans except as a source of contaminants, with some notable exceptions (e.g., Newman, 2015). This ecotoxicology chapter, imbedded in a book focused on human or biomedical toxicology, describes the younger science of elucidating chemical effects in natural systems. While ecotoxicology has features distinct from biomedical toxicology, it is important to consider parallelisms in the two fields and, more broadly, interconnections between human health and ecological integrity, or health. While obviously related, biomedical and ecological toxicology have historically exhibited relatively little coordination or collaboration among scientists across these fields. This is likely due to a number of reasons, including the different levels of biological organization considered, as well as different academic cultures populating the two fields. However, it is questionable if this gulf has been in the best interest of understanding chemical effects, and ultimately protecting both human and ecological health. This concern has prompted several broad discussions intended to bridge this divide and enhance interdisciplinary natural and social scientific research in these areas (see reviews by Costanza et al. [1992], Di Giulio and Monosson [1996], and Di Giulio and Benson [2002]).

This gulf has resulted in two fields that, while largely disconnected, parallel one another and share common paradigms such as dose–response, toxicokinetics, mechanisms of action, and risk assessment frameworks. However, by generally ignoring how chemicals and other anthropogenic stressors that degrade ecosystems can ultimately impact human health and well-being, and vice versa, an opportunity to holistically understand the results of environmental contamination is lost. Miranda et al. (2002) developed a conceptual model for elucidating the interconnections paradigm that links natural and social systems in a circular manner with continuous feedbacks, as opposed to parallel linear models (exposure to response, in either humans or ecosystems) that dominate toxicology currently. In this conceptual model, the natural system produces both positive outputs (such as natural resources and raw materials) and negative outputs (e.g., hurricanes and disease vectors) to the social system. The culture and institution of the social system in turn transforms the natural system outputs in various ways and subsequently delivers various positive outputs (consumer goods, conservation efforts) and negative outputs (pollution, deforestation) to the natural system. These outputs influence the quantity and quality of life (human and nonhuman) of the natural system, and the circular flow of resources continually creates conditions that influence the well-being of individuals, societies, and ecosystems, now and in the future.

This rather abstract model formalizes the interconnections between human and ecological health that most of us intuitively sense. Some of these connections, in the context of environmental pollution, are obvious. Chemical contamination of seafoods valued by humans is one example. Others are less clear but potentially very significant, such as human impacts on aquatic systems that foster the propagation of human disease vectors, or human impacts on global climate that may concomitantly impact humans and ecosystems in varied and complex ways. Also important to consider is the matter of human perceptions of their environment; people's sense of the health of the environment in which they live (whether their perception is correct or not) can have substantial impacts on their mental and physical health (O'Keefe and Baum, 1996). As noted by Kendall et al. (2001), "the indirect effects of environmental pollution may, in the end, be more important than the direct effects for human health."

There are significant indications that these fields are converging and meaningful interactions are increasing. The concept of "One Health" has gained traction in recent years and is very relevant to this discussion (see Zinsstag et al. [2015]). This concept originally emphasized the role of animals in disease transmission to humans (zoonoses), but broadly recognizes the relationship between ecosystem health and human health. The *EcoHealth Journal* is devoted to this topic. The inclusion of an ecotoxicology chapter in this text is also favorable evidence. This trend is motivated in part by the genomics revolution that provides powerful methods for evaluating fundamental biological similarities across species, including those employed in biomedical and ecotoxicological research. Research in this area has revealed genetic similarities, or conservation, in many genes and the proteins they code for that are important to organismal adaptations and impacts due to environmental stressors, including chemicals (Eaton et al., 2006). Certainly many important species differences also exist that contribute to the great complexity of understanding human–ecological interconnections, but as pointed out by Winston et al. (2002), "in the final analysis, the biological similarities across living systems are probably more impressive than the differences." Discussions among diverse scientists of the promises, limitations, and potential applications of genomics for elucidating cross-species extrapolations are provided by Benson and Di Giulio (2006). Such cross-fertilizations among biomedical and environmental scientists, as well as social scientists and policy makers, are likely to enhance all areas, and catalyze the integrated protection of human and ecosystem health.

AIR POLLUTION IN PERSPECTIVE

The second half of the 20th century was marked by remarkable changes in how the public viewed its relationship to the environment. In the 19th and early 20th centuries, national pride and prosperity in Western countries were often depicted as an expanse of urban factories with smokestacks belching opaque dark clouds of industrial effluent into a neutral blue sky. But the price of that unchecked human progress led to several air pollution catastrophes highlighting the profoundly detrimental impact that reckless prosperity could have on the environment. These images of "modern" life gradually gave rise to public outcry for governmental action to protect air quality and public health—a challenge to industry that had been focused on economic growth alone. The ensuing 50 years of regulatory legislation in the United States and Western Europe along with cost efficient innovations by the private sector have remade this industrial image in most technologically developed nations.

Ironically, as regulatory control measures began to reduce emissions from stationary industrial sources of air pollution, highways to "open spaces" and urban flight took many people to the suburbs with its cleaner air and safe, comfortable lifestyle. Meanwhile, the developing world saw little of this growth and what grew was frequently cast-off old technology and variants of exploitation by the Western corporations attracted by abundant resources, a cheap work force, and fewer regulations or constraints. This situation has persisted in the 21st century but is evolving with broader globalization of improved technology and communication.

The change in land use and demography in the United States in the 1950s and 1960s altered the national character and distribution of air pollution. The commute from suburban home to city workplace back to suburban home led increasingly to congested thoroughfares, whose emissions contributed to a photochemical cauldron of oxidant air pollution around expanding metro-suburban areas. Moreover, postwar population growth and rising expectations

*This chapter has been reviewed by the U.S. Environmental Protection Agency, and approved for publication. Approval does not signify that the contents necessarily reflect the views and the policies of the Agency.

for a better (peace-time) standard of living led to unrestrained consumption, including inexpensive gasoline for commuting and recreation. Similar patterns of unrestrained growth are occurring in developing nations throughout the world.

Today, the search is worldwide for cheap oil to fuel transportation and goods movement and international sources are increasingly prominent. For nontransportation sectors of industry and electricity generation, low cost and domestic availability have brought coal to the top of the energy pyramid in many countries. Other energy sources, natural gas and biomass in its varied forms, are being intensively explored to meet the energy demands of modern life. Most notable as a potential major resource is natural gas which is being recovered through less conventional methods (e.g., fracking), which has brought about a revolution in energy resources in the United States. Decades to come will see an evolution in our energy portfolio driven by cost and access, environmental impacts including climate change, and technological innovation. Nevertheless, so long as organically derived fuel is combusted to derive energy, its potential for impact on air quality and on public health and the environment will remain.

While great strides have been made in balancing regulation and technology to reduce emissions from stationary and mobile sources, unsatisfactory air quality continues to impose a risk to public and environmental health in developing countries and even in highly developed countries throughout the world. For example, more than half the U.S. population resides in counties that are not in compliance with current National Ambient Air Quality Standards (NAAQS) (Fig. 31-1). These noncompliant areas correspond well with where people live and work and reflect the redistribution of population growth from major urban and industrial centers. Air pollutants can also be transported across many miles such that previously pristine, rural areas have measurable pollution above their historic background levels. Indeed, as the developing world grows industrially, air pollution now is intercontinental with transport through the atmosphere via pathways close to the Earth's surface as well as the upper atmosphere. Emissions of precursors of ozone can come from hundreds of miles away and contribute to local pollution levels; likewise other emissions such as sand storms in Asia can travel many thousands of miles from the original sources.

While episodes of extreme air pollution are rare in the Western world today, occasionally, unusual meteorological stagnations exaggerate typical air pollution patterns both in the levels of pollutants and their expanse (e.g., 1995 in the United Kingdom and Western Europe; 2017 in Delhi). Likewise, in specific locales prone to stagnations due to topography (e.g., Utah Valley through the 1980s to 1990s) or where there exists a single dominant source (e.g., port areas, transport terminals, or smelters), repeated episodic or even patterned poor air quality can impact public health. From a broader public community perspective, typical exposures are characterized by prolonged periods of relatively low, cyclic levels of complex mixtures of photochemically transformed industrial and mobile emissions with occasional moderate excursions due to weather patterns. As pollution now extends even into remote and wilderness areas, significant damage to flora and crops can also occur.

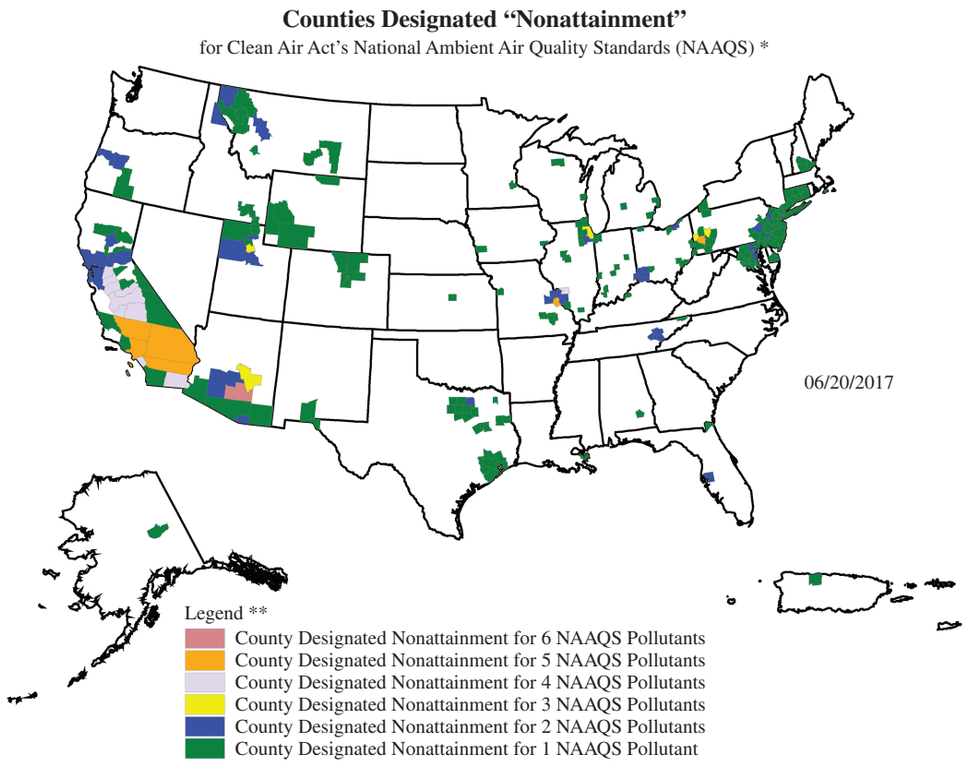

Figure 31-1. *Counties in the United States not in attainment (current as of July 2017) for the NAAQS criteria pollutants O_3, $PM_{2.5}$ and PM_{10}, SO_2, and Pb at their latest promulgated standard* (available at: https://www.epa.gov/green-book). There were no designated nonattainment areas based on the 1971 NAAQS for CO and NO_2. As of 2010 a revised NAAQS for NO_2 was promulgated—designations are not completed. The composite map can be found at: https://www3.epa.gov/airquality/greenbook/mapnpoll.html.

The situation in many developing countries experiencing rapid population growth, industrialization, and economic expansion is reminiscent of the urban, industrial pollution in the United States and Europe more than half a century ago. The lessons of Western industrial nations and the consequences of inadequate air pollution control in some countries have not necessarily outweighed economic drivers or public health concerns. For example, despite being a modern economic center, two marathoners died in Hong Kong in February 2006 while running on a weekend during a protracted period of severe air pollution. Just as in U.S. history, the urban air in rapidly industrialized nations simply reflects poor air quality management and the desire to prosper economically. Air pollutants levels in some of the developing urban centers can run 10 or more times those of the U.S. today, and their expanding worldwide distribution contributes substantially to the global burden of many air pollutants such as mercury, particulate matter, sulfate/SO_2, and major global warming pollutants such as black carbon, CO_2, and methane. One example of episodic air pollution occurs in India when the postharvest burning of agricultural residue and Diwali festival celebrations coincide. A willingness to balance worldwide economic growth and industrialization using lessons learned from the misadventures of the Second Industrial Revolution and the Age of the Automobile will determine the impact of the "new" global economy on the health of both the Earth and its inhabitants.

Over the last several decades, there has been growing awareness and documentation of the disparities in health across the globe. These disparities are linked to poverty, access to clean food and water, as well as health care and education, autocratic governments, wars, and all that is associated with these population deficiencies and stressors. Globally scientists, physicians, and various public health agencies—led by the World Health Organization (WHO)—have taken yearly accounting of disease, deaths, births, and various related data to compile and publish a series of articles in *The Lancet*, every 2 to 3 years, providing a comprehensive assessment of global health that is called the *Global Burden of Disease (GBD)* (Murray, 2016). Air pollution—both indoor and outdoor—and tobacco smoke account for a large fraction of chronic cardiopulmonary disease, the major cause of death in what is estimated as 8 million deaths per year. Importantly, inhalation of toxic inhalants is among the five top killers around the planet.

The problem facing many parts of the developing world ties closely to national domestic culture and economy, as well as to the level of technological sophistication. Prime among these problems is exposure to carbon and soot from combustion of biomass in cooking and heating in domestic stoves. Approximately 3 billion people worldwide use biomass for home cooking in households with little ventilation. Among the 7 to 8 million deaths per year resulting from these exposures are primarily women who are exposed day in and day out over many years, often with their infant children by their sides. Understanding the intersection of technological as well as socioeconomic and political challenges will be at the core of any resolution to these issues.

In the developed world, air pollution has a long history, but in the last century it has been largely tied to technological and energy evolution. Estimates of smoke, which could be seen with the naked eye, could be collected and compiled as general indices of haziness or the darkness of a spot on a filter. Many people experienced irritancy, choking or soot accumulation around their noses which eventually drove interest into learning whether the soot was unhealthy. Then when there were health symptoms, interest in causation over time drove science to focus more on individual pollutants associated with some source or haze to better understand the linkages with health and to aid in mitigation of effects. In turn, this knowledge was used to develop both public health standards and to establish regulatory controls—an evolution in public spirit and perseverance that took decades.

Despite the obvious complexities of urban air pollution, it was felt that single pollutant research and regulations were the best path to understanding what was going on, and indeed, this approach brought great strides in providing the compelling information needed to drive both public and political sentiment. However, research agendas have advanced and have taken the challenge to study multipollutant interactions and transformation of individual pollutant components within complex photochemical, atmospheric systems—a truer reflection of real-world exposure complexities. These multipollutant approaches entail sophisticated statistical models and empirical study designs, all with the goal of a more complete systems-based understanding of air pollution and risk to maximize benefits while minimizing costs and unintended consequences.

This chapter presents an overview of the current state of knowledge regarding air pollution and its ensuing impacts on human health, and the role of toxicology and translational biology in unraveling the complexities to allow for informed assessment of risk. As such, the contextual complexities of regulatory decisions and risk assessment are also addressed. The intent is to provide the reader with both a fundamental knowledge and appreciation of the nature of the problem, how traditional and modern-day approaches aid in this understanding, as well as a sense of the uncertainties in need of future investigation to resolve issues even before they arise.

A Brief History of Air Pollution and its Regulation

For most of history, air pollution has been a problem of microenvironments and domestic congestion. The smoky fires of early cave and hut dwellers choked the air inside their homes, and even when the emissions were vented outdoors, they simply combined with those of the neighbors to settle around the village on damp cold nights. With urbanization and a concomitant decrease in forest wood as a source of fuel to heat and cooking, the need for energy led to the burning of easily accessible, dirty coal and the ambient release of sulfurous, sooty smoke. Industrialization brought kilns to make quicklime for construction and metal smelters needed for the development of progressive "modern" cities, only to push smoke and chemical emissions into the air. Unfortunately, the city dwellers who worked near these industries had to endure the bad air, while those of wealth frequently had country homes to which they could escape. The poor quality of urban air has been captured historically by many writers including Charles Dickens, who noted London's fogs in his writings, all the way back to the ancients like Seneca, the Roman philosopher, who in AD 61 wrote: "As soon as I had gotten out of the *heavy air* of Rome, and from the *stink* of the chimneys thereof, which being stirred, poured forth whatever *pestilential vapors and soot* they had enclosed in them, I felt an *alteration to my disposition*" (emphasis added: Miller and Miller, 1993).

Historically, efforts to regulate air pollution have, like today, competed with concerns for national, regional, and industrial economies, and as a result, they have evolved slowly. Early on, in the time of Greece and Rome, individual civil suits could be levied against local polluters, although these were of marginal success. Beginning in the 13th century, community-based outcries received some recognition by governing officials; one example was the banning of "sea coal" from lime kilns and domestic heaters in London by Edward I. Enforcement, however, was not effective and the populace largely resigned itself to polluted air as part of urban life. By the 17th century, England, in the middle of several decades that some refer to as "the little ice age," depleted its forest wood resources, which only increased reliance on

sea coal for domestic heating. Meanwhile Percival Pott's discovery that chimney soot was related to the incidence of scrotal cancer in chimney sweeps led to some in the health community to recommend: "Fly the city, shun its turbid air; breathe not the chaos of eternal smoke . . ." (Brimblecombe, 1999)—essentially the same advice advanced by Seneca 1600 years earlier. In the late 18th century, the industrial revolution, which was powered by the burning of "cleaner" mined coal, added a second dimension to urban air pollution. These emissions were more acidic and hung in the air longer than the fluffy soot of the cheaper sea coal. Continued soiling of buildings and damage to nearby crops brought community boards to address sanitary reforms to cut the worse of the pollution peaks and episodes, but any gains were soon offset by growth. By the end of the 19th century and into the early 20th century, power plants were being built to provide energy for factories and eventually to light homes in the Western world. Steel mills and other industries proliferated along riverbanks and lakeshores, oil refineries rose in port cities and near oil fields, and smelters roasted and refined metals in areas near large mineral deposits.

By 1925, air pollution was common to all industrialized nations in the Western hemisphere. However, people slowly grew less tolerant of the nuisance of acidic-soot corrosion of all exposed surfaces and the general discomfort that came with smoky air—this acidic, sooty form of air pollution was termed *reducing* air pollution because of its reducing chemical nature. Public surveys were initiated—in Salt Lake City in 1926, New York City in 1937, and Leicester, Great Britain, in 1939—to bring political attention to the problem and promote the implementation of controls (Miller and Miller, 1993). However, it was the cumulative impact of the great air pollution disasters in the Meuse Valley, Belgium, in 1930; Donora, Pennsylvania, in 1948; and the great London fog of 1952 that indicted air pollution as a health risk. In the United States, California was already leading the way with passage of the Air Pollution Control Act of 1947 to regulate the discharge of opaque smokes. Visibility problems in Pittsburgh during the 1940s had also prompted efforts to control smoke from local industries. At the national level, however, it was the initiative of President Truman that provided the federal impetus to deal with air pollution. His early efforts culminated in congressional passage of a series of acts starting with the Air Pollution Control Act of 1955 under the Eisenhower administration.

The prosperity within North America in the late 1950s and the accompanying suburban sprawl introduced the third and perhaps most chemically complex dimension of air pollution. The term *smog,* though originally coined to describe the mixture of smoke and fog that hung over large cities such as London, was curiously adopted for the eye-irritating photochemical reaction products of auto exhaust that blanketed cities like Los Angeles and Mexico City. Early federal legislation addressing stationary sources was soon expanded to include automobile-derived pollutants in the United States (the Clean Air Act of 1963, amended in 1967, and the Motor Vehicle Air Pollution Control Act of 1965). The landmark Clean Air Act Amendments (CAAA) of 1970 evolved from the early legislation, and despite being only an amendment to the CAA, it was revolutionary. It recognized the problem of air pollution as a national issue and set forth a plan to control it. The Act charged the newly instituted U.S. Environmental Protection Agency (U.S. EPA) with the responsibility to protect the public from the hazards of polluted outdoor air. Seven "criteria" air pollutants (ozone (O_3), sulfur dioxide (SO_2), particulate matter (PM), nitrogen dioxide (NO_2), carbon monoxide (CO), lead (Pb), and total hydrocarbons—the last now dropped from the list, leaving six criteria pollutants) were specified as significant health hazards in need of *individual* NAAQS. Sections 108 and 109 of the CAA mandates a process for review of the NAAQS every 5 years as to the adequacy of the existent standard to protect human health (Table 31-1), although adherence to this schedule has generally not been achieved due to the rigor of the process itself (U.S. EPA, 2005). The explosion in the literature databases for the criteria pollutants and the extensive review and commentary process has typically led to delays in completing the process on schedule. In 2006, however, this process was streamlined through the creation of an Integrated Science Assessment (ISA) to replace each Criteria Document where the findings since the last assessment could be integrated with older studies (summarized with the foundation literature confined to tables and an appendix). This ISA is combined with a Risk and Exposure Assessment into a Policy Assessment to develop a range of proposed standards based on risk analyses. As per the CAAA of 1970, the U.S. EPA Administrator considers proposals from both "evidence" and "risk" based assessments to establish policy and set the NAAQS. Regarding the Primary NAAQS, only health criteria can be considered in the development of the standard, including safety considerations for potentially susceptible groups. The Secondary NAAQS consider agricultural and structural welfare. Economic impacts are not to be involved in standard setting process itself—only in assessing the cost of the implementation procedures. Other hazardous air pollutants (HAPs), of which there were 8 listed in 1970, were also to undergo health assessments to establish emission controls—today there are 188 (see the section "Hazardous Air Pollutants"). The CAAA of 1970 was by far the most far-reaching legislation to control air pollution to date.

Disasters involving HAPs have occurred and the accidental release of 30 tons of methyl isocyanate vapor into the air of the shanty village of Bhopal, India, on December 3, 1984, killed an estimated 3000 people within hours of the release, with several thousand delayed deaths and 200,000 injured or permanently impaired. The tragedy shocked the world, and raised the issue of HAPs in the United States to a new level of concern. While such a disaster

Table 31-1

National Ambient Air Quality Standards*

POLLUTANT	PRIMARY/ SECONDARY	AVERAGING	TIME LEVEL
Sulfur dioxide	Primary Secondary	1 hour 3 hours	75 ppb 0.5 ppm

has never struck the United States, accidental industrial releases or spills of toxic chemicals are surprisingly common, with 4375 cases recorded between 1980 and 1987, inflicting 11,341 injuries and 309 deaths (Waxman, 1994). The Toxic Release Inventory (TRI) of 650 chemicals reported annually by industry is required by EPA and suggests a decrease in releases (approximately 9% in 10 years across land, water, and air), but these data are self-reported and do not include most of the 80,000 low-volume chemicals in use today.

The HAPs, which had been the stepsister of the criteria pollutants for more than a decade after the passage of the 1970 CAA, have since garnered more public and policy attention. There is concern not only for the acute effects of accidental releases of fugitive or secondary chemicals—such as phosgene, benzene, butadiene, and dioxin into the air of populated industrial centers—but also for potential chronic health effects, with cancer often being the focus of attention. The slow progress of regulatory decisions on HAPs (only eight between 1970 and 1990) led to a mandated acceleration of the process under the CAA amendment of 1990. Section 112(b) currently lists 188 chemicals or classes of chemicals for which special standards and risk assessments are required. The chemicals listed are those of greatest concern based on toxicity (including cancer) and estimated release volumes. Currently, there is a list of 33 HAPs from the list of 188 that are deemed to be of greatest concern, so-called a list of the "dirty 30." Emissions of HAPs are mandated for control to the maximal achievable control technology (MACT), and any residual health risk after MACT is to be considered in a separate quantitative risk assessment. The database for this process utilizes existing knowledge or, if necessary, mandates further research by the emitter. While many of these chemicals are now better controlled in the United States than in the past, residual risk estimates are yet to be completed for many HAPs. The database from which these assessments are made is called the Integrated Risk Information System (IRIS; U.S. EPA, 2016) and currently contains 754 chemicals which have completed assessments.

Emissions from motor vehicles include several HAPs (e.g., benzene and butadiene) as well as NAAQS pollutants (e.g., CO, NO_x, and PM), but in the United States these are addressed primarily under the CAA Title II, Emission Standards for Mobile Sources. The health data may draw from IRIS but the regulatory aspect is specific to this legislation. The reduction of emissions from mobile sources is complex and involves both fuel formulation and engine/vehicle reengineering. Refinements in combustion engineering are ongoing making use of advanced computerized ignition and timing, but fuel properties have drawn most recent attention for improvement. For example, to reduce wintertime CO, several oxygenates (including ethers and alcohols) have been formulated into fuels both to reduce cold-start emissions and enhance overall combustion. Perhaps the most prominent of the ethers is MTBE (methyl tertiary butyl ether), which became a controversial additive in the early 1990s, arising in part from odor and reports of asthma-like reactions by some individuals during auto refueling. However, the controversy took an unexpected twist; MTBE was removed from fuel, not because health concerns associated with airborne exposure but rather due to leakage from service-station storage tanks. Ironically, this prescribed remedy for an air problem evolved into an unexpected problem: groundwater contamination. This example illustrates the broad complexity of all pollution control measures in that unappreciated factors can transcend engineering or other targeted features if a broader systematic assessment is not undertaken. Nevertheless, fuel additives have been developed to boost octane ratings of fuels and/or improve engine performance and combustion (e.g., organic oxygenates, methylcyclopentadienyl manganese tricarbonyl (MMT), and platinum compounds for diesel). These additives are reviewed under Title II because of concerns regarding the potential changes in combustion product reactivity or the introduction of metals into the environment, reminiscent of use of lead in fuels from the 1930s to the 1970s, when lead fuel additives were banned in the United States.

Internationally, the magnitude and control of air pollution sources vary considerably, especially among developing nations, which often forgo concerns for health and welfare because of cost and the desire to achieve prosperity. Fig. 31-2 illustrates the international variation in $PM_{2.5}$ air pollution, including the world's megacities with

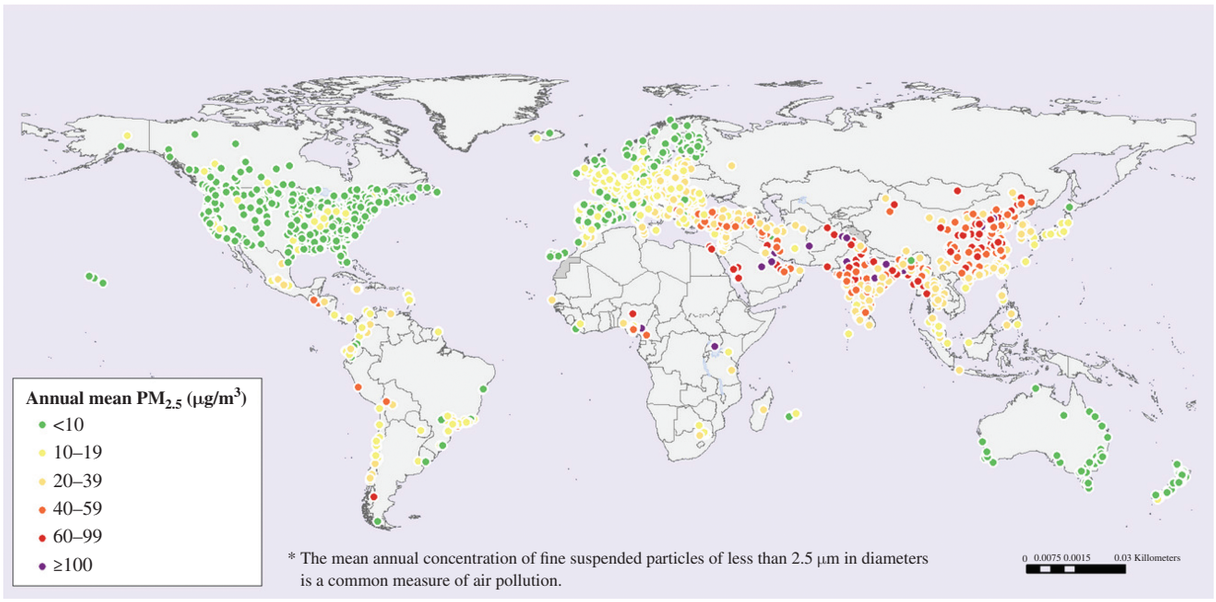

Figure 31-2. *Concentration of $PM_{2.5}$ in nearly 3000 urban areas in the world.* Data are from the World Health Organization's outdoor air pollution database from 2008 to 2015. An interactive map for the WHO database is available at: http://maps.who.int/airpollution/. (From WHO Map Production: Information Evidence and Research [IER]).

major air pollution problems. The political upheaval with the reunification of Eastern Europe revealed the consequences of decades of uncontrolled industrial air pollution, which today are largely rectified. While vast improvements are now evident in this area, as industries are being modernized and emissions controlled, many Asian, African, and South American cities have virtually unchecked air pollution fueled by the desire for economic growth and expansion of low-cost labor. Many nations have adopted WHO guidelines (WHO, 2005) on air pollution as a rational basis for guiding control measures, but the lack of binding regulations and/or unconstrained economic opportunities impede significant controls and improvements.

In addition to local socioeconomic and political concerns, emissions of air pollutants have spawned problems of "international pollution." Long-range transport of polluted air masses from one country to another has been anticipated as a global issue for many years (Wuebbles et al., 2007). This issue was the subject of some controversy between Canada and the United States in the late 1980s and into the 1990s as a result of the air mass transport of acid sulfates from industrial centers of the midwestern United States to southern Ontario. However, reduction in SO_2 emissions somewhat relieved this tension (Fig. 31-3). Improvement in NO_x, also a product of stationary source fossil fuel burning, is also apparent. Long-range transport of air pollution also occurs on a global scale. Importantly, growing prosperity in China has led to enormous growth in its power sector and coal combustion resulting in transoceanic transport of airborne mercury such that transported mercury now accounts for a majority of mercury deposition in waterways and land across the globe (Ci et al., 2012). Similarly, dust or sand storms originating in arid and semi-arid regions of Africa and Asia can also undergo global transport (Fig. 31-4).

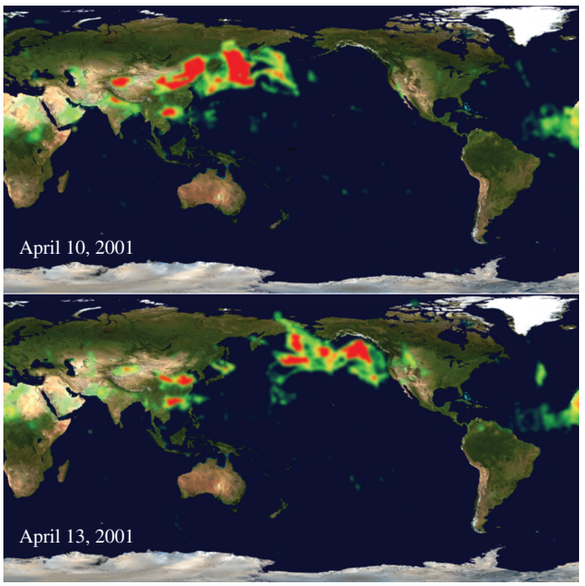

Figure 31-4. *Global images of an Asian dust cloud captured by NASA's Earth-Probe TOMS satellite.* The April 10, 2001 panel shows the dust cloud over China and traveling east and the April 13 panel shows the cloud reaching the west coastline of North America. (Images courtesy of NASA's GSFC/Earth Science Data and Information System [ESDIS].)

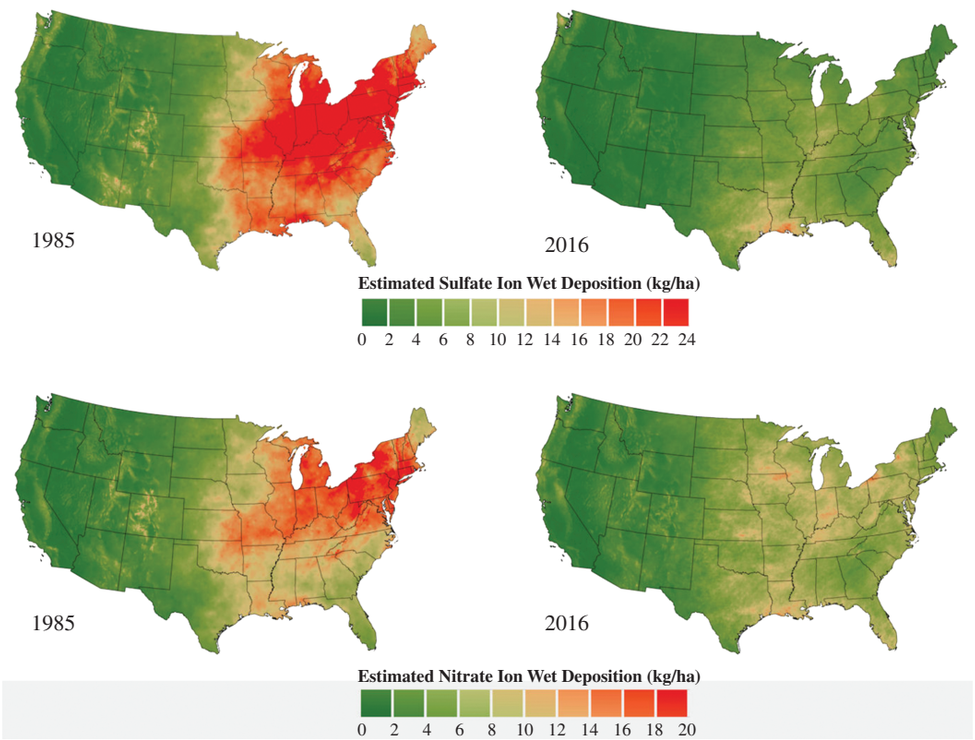

Figure 31-3. *Reduction in ambient particulate sulfate and nitrate concentrations between 1988 and 2008 in the eastern half of the United States (from CASTNet monitoring data).* Sulfates and nitrates arising from industrial centers of the Midwest contribute to acid rain deposition (see Fig. 31-14). Sulfates are readily dispersed by winds toward the eastern half of the country. Nitrates arise from the industrial centers as well as from motor vehicles metropolitan areas and show both a local and dispersed pattern. TOOLS TO ASSESS RISKS ASSOCIATED WITH AIR POLLUTION

Risk assessment is a formalized process, originally described in the landmark 1983 National Research Council Report, whereby toxicity, exposure, and dose-dependent outcome data can be systematically integrated to estimate risk to a population. Fig. 31-5 provides a modified version of the paradigm of the NAS (NRC, 2009), incorporating recent interest in providing evidence of "accountability" that the regulations indeed do have impacts—presumably improvement. The health database for any air pollutant may comprise data from animal toxicology, controlled human studies, and/or epidemiology. But, because each of these research approaches has inherent strengths and limitations, an appropriate risk assessment of an air pollutant requires the careful integration and interpretation of data from all three methodologies. Thus, one should be aware of the attributes of each (Table 31-2).

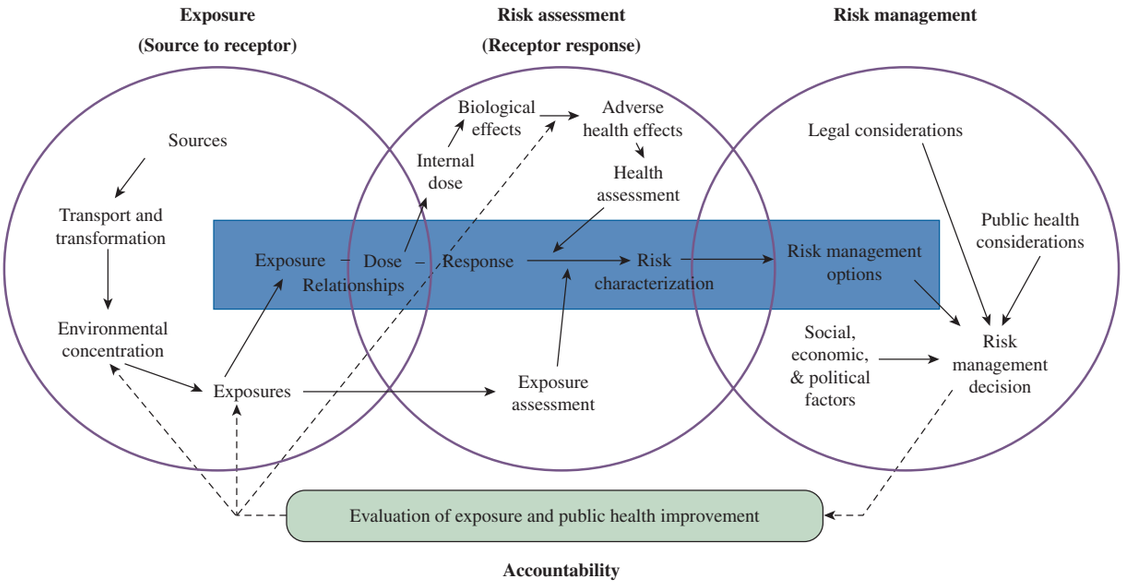

Figure 31-5. *NRC risk assessment paradigm.* Components of *risk assessment* within the left circle provide data to development of *risk management* as depicted in the right circle, modified to include an "accountability" component as a means to address air quality management impacts on the process risk reduction. (From the National Research Council [2009].)

Table 31-2

Strengths and Weaknesses of Disciplinary Approaches for Obtaining Health Information

DISCIPLINE	POPULATION	STRENGTHS	WEAKNESSES
Epidemiology	Communities	Natural exposure	Difficult to quantify exposure Many covariates
	Diseased groups	No extrapolation Isolates susceptibility trait Long-term, low-level effects	Minimal dose–response data Association vs. causation
	Field/Panel groups	Good exposure data Fewer covariates Focus on host traits Utilizes clinical evaluations	Usually short-term Volunteers Expensive
Clinical studies	Experimental Diseased subjects	Controlled exposures Few covariates Isolates susceptibility trait Cause–effect	Artificial exposures Acute effects only Hazards Volunteers
Toxicology	Animals	Maximum control Dose–response data Cause–effect	Human extrapolation Realistic models of human disease?
	In vitro systems	Rapid data acquisition Mechanisms	In vivo extrapolation

Epidemiologic studies reveal associations between exposure to a pollutant(s) and the health effect(s) in the *community* or *population* of interest. Because data are garnered directly under real-world exposure conditions and often involve large numbers of people, the data are of direct utility to regulators assessing pollutant impacts. With proper design and analysis, studies can explore either acute or long-term exposures and theoretically can examine spatial and temporal patterns in mortality and morbidity, both acute and chronic, especially if these responses appear disproportionately in population subsets (i.e., sensitive groups). Why, then, is this epidemiological approach to the study of air pollution not the exclusive choice of regulators in decision making? The problem is that it is difficult to control confounding personal variables in the population. Factors such as genetic diversity and lifestyle differences among individuals, and population mobility are difficult to control, but perhaps most problematic is the lack of adequate exposure data—especially on a personal basis. Exposure assessment is often one of the major weaknesses of an epidemiologic study, not only because of the difficulties of assessing exposure (as a measure of dose) to the pollutant of interest, but also because it is difficult to segregate a single pollutant from correlated co-pollutants and other environmental influences, such as meteorology. Thus, only associations, and not causality, can be drawn between the broad-based exposure data and effects observed in epidemiology studies. Causal relationships are sometimes inferred in the presence of strong statistical significance, but such determinations are likely to be criticized. However, advances in exposure estimation and study design and analysis (e.g., time series) have allowed epidemiologists to examine relationships with greater confidence and specificity. These models limit the impact of covariates and longer time-based influences and thus allow epidemiologists to tease out effects of short-term pollution not accessible formerly (Zeger et al., 2006). Similarly, newer approaches that employ field studies—sometimes called *panel studies*—incorporate time-series design and multiple-regression analyses of more focused and complete exposure data (ideally personal) and targeted clinical endpoints in the exposed population under study. The endpoints often derive from empirical human and animal studies and therefore have a priori conceptual ties. The advent of new genetic approaches for characterizing polymorphisms of potentially influential traits opens the genomic door for assessing gene–environment interactions (London and Romieu, 2009). Such studies have focused on individual genetic polymorphisms (Tujague et al., 2006) or utilized "fishing expedition–like" genome-wide approaches to discover polymorphisms associated with oxidative stress (Minelli et al., 2011) or lung cancer (Hosgood et al., 2015). These factors may well underlie a significant portion of the human susceptibility to air pollution. Novel approaches such as this are evident in the most recent studies of PM air pollution (see the section "Susceptibility").

Studies that involve *controlled human exposures* have been used extensively to evaluate the criteria air pollutants regulated by the U.S. EPA. Because most people are exposed to these pollutants in their daily lives, human volunteers can be ethically exposed to them in a highly controlled fashion (except for Pb, which has cumulative and irreversible effects). Exposures are conducted in a controlled environment (usually in a chamber or with a mask or mouthpiece) and are generally of short or limited repeat durations, given assurances that all responses are reversible. Clearly, data of this type are very valuable in assessing potential human risk, since they are derived from the species of concern (i.e., human) and are rooted in well-established clinical knowledge and experience.

Suspected "susceptible or sensitive" individuals representing potential higher-risk groups can also be studied to better understand the breadth of response in the exposed public. However, clinical studies have several practical limitations. Ethical issues are involved in every aspect of a clinical test; potentially irreversible effects and carcinogenicity are always of concern, along with the definition of an acceptable level of hyperresponsiveness in so-called sensitive individuals who volunteered to participate in the study. Likewise for any test subject, there are obvious restrictions on the invasiveness of biological procedures, although sophistication in medical technology has made accessible a large array of molecular biomarkers from peripheral blood and nasal, bronchial, and alveolar lavage fluids as well as biopsied cells from airway segments (Mirowsky and Gordon, 2015). With the advent of cutting-edge genomic and proteomic high-throughput technologies, new tools are emerging to identify responses in humans and the relationships to innate susceptibility. Obviously, the issue of cost, the limited numbers of subjects that can be practically evaluated, and the inability to address chronic exposure issues remain constraints on human clinical testing. Where partnerships with animal toxicology studies have been established, studies in laboratory animal species can sometimes provide ethical justification for at least limited direct human exposure for addressing critical questions. Analogously, in vitro studies in both human and animal cell and tissue systems, often augmented with similar genomic tools, allow the elucidation of mechanisms of toxicity. These basic biological responses inform extrapolation models that link animal data to humans, and they support the relevance of nonhuman studies and preclude risks that may reside in human studies with some toxic air pollutants (see the section "Hazardous Air Pollutants").

Animal toxicology is used to predict or corroborate, through plausible mechanisms, suspected effects in humans. In the absence of human data, animal toxicology constitutes the essential first step of risk assessment: *hazard identification*. Animal toxicology is often required before any controlled human exposure study can be conducted. It is particularly useful in elucidating pathogenic mechanisms involved in toxic injury or disease, providing basic knowledge that is critical to extrapolating databases across species, estimating uncertainties, and determining the relevance of information to humans. Knowledge of the toxic mechanism(s) provides the underpinnings to the "plausibility" of findings in the human context and, under carefully defined and highly controlled circumstances, may allow *quantitative* estimates of risk to human populations. Animal toxicology studies have been used to investigate all of the criteria air pollutants and many of the HAPs as well. The strength of this discipline is that it can involve methodology that is not practical in human studies and can provide more rapid turnaround of essential toxicity data under diverse exposure concentrations and durations. The minimization of uncontrolled variables (e.g., genetic and environmental) may be the greatest strength of the animal bioassay.

Animal-to-Human Extrapolation: Issues and Mitigating Factors

The clear limitation of animal studies in human risk assessment lies in the unknowns of biology and exposure that weaken the extrapolation of findings in animals to the day-to-day human life scenario. Ideally, a test animal is selected with knowledge that it responds in a manner similar to that of the human (*homology*). *Qualitative* extrapolation of homologous effects is not unusual with many toxic inhalants, but *quantitative* extrapolation is frequently clouded by uncertainties of the relative *sensitivity* of the animal or specific target tissue compared with that of the human. Uncertainties about the target tissue dose also loom large, constituting the first obstacle to quantitative extrapolation, see the section "Extrapolation." With

respect to the target tissue dose, however, most animal toxicologists make every effort to keep exposure concentrations at 5- to 10-fold that of the anticipated human exposure until appropriate dosimetric data can be ascertained. An often-overlooked issue is that the dose to the target (lung region) for the test animal is frequently less than that of the human under similar exposure conditions—especially when exposures are conducted during dormancy for the animals (Wichers et al., 2006). Most human inhalation studies involve exercise exposure paradigms where increased ventilation augments dose. Thus, in the absence of exercise, higher doses may be needed to achieve a statistically significant group response among a limited pool of genetically similar animals (typically with an *n* of 6 to 10) to represent a large population effect. However, it must be appreciated that mechanisms may well differ at different dose levels and some responses may be misleading if assessed only at the higher dose levels. Despite these limitations, however, animal studies have provided the largest database on a wide range of air toxicants and have proven utility in predicting adverse human responses to chemicals. New high-throughput technologies offer great promise in shortening the toxicity assessment process and reducing costs of both the test process and the consumption of animals, but it remains to be seen how this new technology aids in the quantitative assessment of toxic inhalants.

To be effective, any health assessment should consider the strengths and weaknesses of the approaches selected to estimate actual toxic risk. In the larger picture, other scientific disciplines can be highly valuable to a more accurate assessment of the impact of air pollution on society. The atmospheric sciences, particularly the chemical and physical sciences, provide insights into exposure by better characterizing what is in the air. Better pollutant characterization, linked to exposure assessment, can only strengthen epidemiological outcome associations. Similarly, better exposure characterization and dose estimates support toxicity evaluations based on biological test systems. In the latter case, the uncertainties of dose relevancy can be reduced and linkages to defined pollutant physicochemical attributes and interactions can be pursued. Recreating realistic exposure environments to the extent possible is invaluable to developing models to estimate human risk.

Lastly, studies of botanical responses to air pollutants are now appreciated more than ever. Not only are commercial and native vegetation affected by pollution but some plant species are being exploited as sensitive "sentinels," warning of the impacts of pollution on both human and environmental receptors. When considered collectively, economists can inform regulators and the public at large of the cumulative impact and adversity of pollution on our quality and standard of living (Martenies et al., 2015). Interestingly, some basic mechanisms (e.g., the involvement of antioxidants) between plants and animals have remarkable parallels.

The value of animal toxicology in inhalation studies is highly dependent on the ability to extrapolate or relate empirical findings to real-world human scenarios. Several factors of study design play into the process of extrapolation (e.g., exposure concentration, duration, and patterns), but most important is the selection of the animal species that will serve as the toxicological model. Therefore, this selection should involve more than considerations of cost and convenience. Whenever possible, effects that are homologous and involve the same mode of action between the study species and the human should guide the decision of the most appropriate test species. For example, if upper airway irritant responses like bronchoconstriction are anticipated (e.g., SO_2 or formaldehyde), then the guinea pig, with its human-like reactive airway reflexes, should be selected over the rat, which is not particularly responsive in this regard. However, if the underlying molecular events in tissue remodeling are of interest, then the rat or mouse might better serve as a model because of cellular mechanistic parallels with human tissue responses. In part, the availability of probes to aid in such studies could factor into the selection of the rodent strain as well. Additionally, as inbred strains of rats and mice differ in their neutrophilic responsiveness to deep lung inhalants (e.g., O_3), contrasting responsiveness or the mode of action may be more revealing and support one strain over another in its selection for study (Costa et al., 1985). Other innate differences in sensitivity among species may also relate to differences in lung structure, regional distribution of cell types having varied metabolism, genetic polymorphisms, or antioxidant defenses. Genetic control of responses such as inflammation have been identified in mice where a specific Quantitative Trait Locus (QTL) on chromosome 17 (*Inf2*) exhibits a more robust neutrophilic response to O_3 (Bauer and Kleeberger, 2010). Thus, when a test animal strain is selected where such nuances are unclear or unknown, the replication of responses in multiple species builds confidence in the finding as being homologous or having species-conserved modes of action that are relevant to the human and bear careful consideration in a risk assessment.

An essential, but often overlooked, part of response extrapolation from species to species is knowledge of the relative dosimetry of the pollutant along the respiratory tract. Significant advances in studies of the distribution of gaseous and particulate pollutants have been made with empirical and mathematical models, the latter of which incorporate parameters of respiratory anatomy and physiology, fluid dynamics, and physical chemistry into predictions of deposition and retention. Empirical models combined with theoretical models aid in relating animal toxicity data to humans and help refine the study of injury mechanisms due to better estimates of the target dose. Fig. 31-6 illustrates the application of such an approach to the reactive gas O_3 and insoluble 0.6-μm spherical particles, as each is distributed along the respiratory tract of humans and rats. Anatomic differences between the species clearly affect the deposition of both gases and particles, but the relative distributions are quite similar. This is not surprising if one argues teleologically that the lungs of each species evolved with similar functional drivers (i.e., O_2–CO_2 exchange and blood acid/base balance), mechanical impediments, and environmental stresses. One needs only a cursory review of the comparative lung physiology literature to appreciate the allometric consistency of the mammalian respiratory tract to meet the challenge of breathing air. This design coherency has provided the fundamental rationale for the use of animal models for the study of air pollutants. With knowledge of ventilation parameters, one should be able to compute nominal tissue doses based on lung surface area using available published data (Anjilvel and Asgharian, 1995).

OVERARCHING CONCEPTS

What Is an Adverse Health Effect?

Establishing criteria to define an "adverse effect" of air pollution is difficult. When relating a health effect to an air pollutant, a response must be appreciated at two levels—that of the individual person and that of the population. Clearly, an effect upon an individual can be beyond an acceptable limit potentially putting that person's overall health in jeopardy; but this response may be lost in an index reflecting a population-based response. The risk to a population reflects the averaging of individual responses or risks and may be measured as a shift in the normal distribution of some index of response for that population. Hence, on average, the entire population may be judged to be at some enhanced risk. These two forms of risk are clearly related, but most often in practice, the population

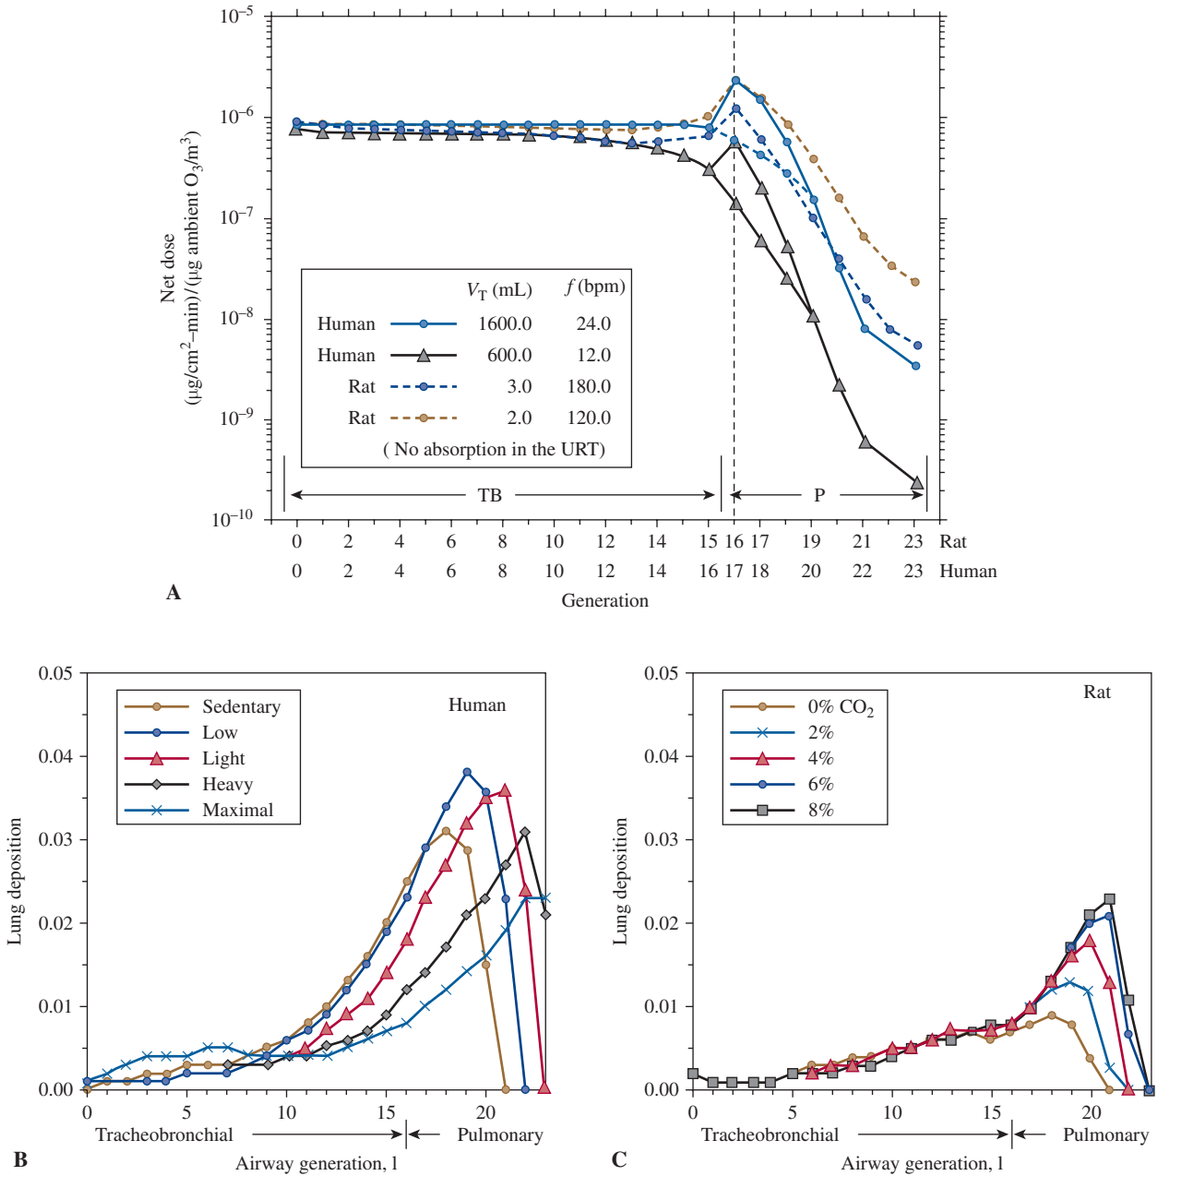

Figure 31-6. *Theoretical (normalized to the concentration in inspired air) uptake curves for the reactive gas ozone in a resting/exercising human and a rat (**A**). Likewise, the percent deposition in the airways of a 0.6-μm insoluble particle in the respiratory tracts of a resting/exercising human (**B**) and rat (**C**).* Eight percent inspired CO_2 in the rat augments ventilation up to threefold. Airway generation refers to that airway branch numbered from the trachea (0). (Panel A is from Overton and Miller [1987], and Panels B and C are from Martonen et al. [1992]. Reproduced with permission.)

risk is considered most appropriate from a public health perspective. Generally, it is also most credibly quantifiable. However, subpopulations that carry some related risk factor may represent a more limited group with unusual risk that too may be quantifiable. Such a group is often called a susceptible subpopulation.

Defining an air pollutant effect as "adverse" within the range of effects that may result from exposure is not always straightforward. Clearly, in humans, some effects would pass uncontested as adverse, for example, death, acute life-threatening dysfunction or disease, irreversible impairments, and pain. In animal models, pathology has traditionally been the hallmark of an adverse effect. In either humans or animals, however, other effects that reflect minor and temporary dysfunctions or discomfort could be argued as not warranting significant or costly concern, especially if the effects are minor and transient with no long-term untoward outcomes. This vein of thought would simply attribute these effects to be within normal physiologic ranges and are readily compensated within functional or biochemical reserve. Thus, if one is to try to assess the impacts of air pollution on health, it is desirable that there exist some objective criteria to define what is indeed adverse based on the nature and the magnitude of the effect under evaluation. Moreover, distinguishing an air pollution effect from other adverse stimuli or disease processes can be complex and fraught with confounding factors, such as smoking and negative lifestyle factors.

Not surprisingly, air pollution impacts have long been focused on the lung as the primary target organ. Regarding acute effects in humans, the American Thoracic Society in 1985 issued a position paper that attempted to define an adverse effect related to air pollution in terms of its impact on lung function (where, e.g., a 10% or more drop in FVC was deemed adverse); at that time, lung function was the primary human health effect that could be studied under controlled inhalation conditions. The definition of "adverse" was revised in 2000, because of the many advances in clinical medicine and empirical health sciences, to include seven broad areas: biomarkers, quality of life, physiologic impacts, symptoms, clinical outcomes, mortality, and population health versus individual risk (ATS, 2000). The summary conclusion states that caution should be exercised in evaluating the many new biomarkers of effect (especially cell and molecular markers), as there is need for validation that *small* changes in these markers represent a progression along a course to disease or permanent impairment. Since that time, further advances in molecular markers and systems assessment of toxic pathways have opened a new dimension of evaluation of health outcomes where their detailed pathogenesis can be examined. Of course, many of the same questions arise as to the criteria used to define when a pathogenic process is qualitatively or quantitatively adverse, but clearly the ability to measure effects and understand their nature and relationship to chronic disease is advancing rapidly. The WHO has also provided a framework to categorize adverse effects in relation to benchmarks. In this framework, a scale is based upon the strength of evidence linking exposure and adverse changes ranging from a posited change to a clear clinical adverse effect. More recently, the European Respiratory Society (ERS) and the ATS wrote a joint statement that addresses adverse effects in additional target organs or systems, such as the reproductive and developmental systems, the brain, and cancer, that are altered by air pollution (Thurston et al., 2017).

Susceptibility

A common thread through these subject areas is the influential role of susceptibility, which can take the form of hyperresponsiveness or loss of reserve. What is a minor reversible effect in the majority of individuals may be a dysfunction that cannot be reversed or compensated in certain individuals (Fig. 31-7). Obvious examples would be cardiopulmonary-compromised individuals who function with little or no reserve. In the end, however, the ATS, ERS, and WHO statements acknowledge the limits of definitions and the importance of value judgment in the final assessment. Implied in this position is that a loss in quality of life due to air pollution as well as enduring its associated effects may also be designated as adverse. As science continues to advance, especially in the realm of molecular biology where small signals can be detected that may forecast an adverse effect or otherwise may identify individuals or groups at risk, the definition of adverse will certainly need reexamination (Thurston et al., 2017). That same sensitivity in measurement that serves to predict an adverse effect must be separated from signals that are essential for homeostasis and the maintenance of life. Clearly, dissecting and defining these phenomena will have implications not only for assessing clinical adversity but also for predictive toxicology.

In actuality, there is no widely accepted definition for a "susceptible" individual and quite frequently the term is used interchangeably with "vulnerable." The U.S. EPA, however, separates the two terms and utilizes "vulnerability" to refer to extrinsic (i.e., nonbiologic) factors (e.g., an increased exposure to ambient air pollutants because one's school is located adjacent to a high traffic volume roadway), whereas "susceptibility" refers to intrinsic biologic factors such as genetics, age, or preexisting disease. Regardless of the precise definition, a susceptible subpopulation encompasses both intrinsic and extrinsic factors that increase the response to air pollution. As demonstrated in both toxicologic and epidemiologic studies, a combination of factors influences the incidence and magnitude of adverse responses of susceptible subpopulations to inhaled pollutants (Table 31-3). For example, over the last 20 years, hundreds of publications have documented an association

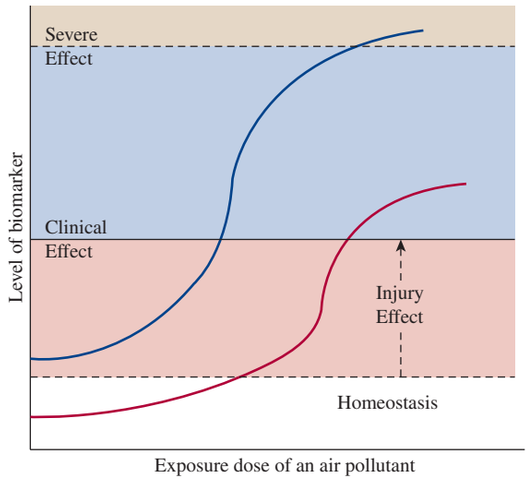

Figure 31-7. *Schematic illustration of the elements of the dose–response to an air pollutant(s) of a susceptible (blue curve) versus a healthy (red curve) individual.* The hypothetical susceptible individual may be more sensitive or may have a *loss of reserve*, either of which results in an *inability to maintain* homeostasis. The *leftward shift or increased slope* in the dose–response curve suggests an increase in responsiveness. Either situation may contribute to sensitivity and the likelihood of enhanced progression from subtle to severe outcomes.

Table 31-3
Factors That Influence the Response of Individuals or Subpopulations to Ambient Air Pollutants

SUSCEPTIBILITY FACTORS	VULNERABILITY/EXPOSURE FACTORS
Preexisting cardiopulmonary disease	Proximity to point source
Genetic factors	Proximity to high traffic volume roadway
Age	Occupation
Gender	Activity level
Race/Ethnicity	Use of air conditioning/building leakiness
Obesity	In utero exposure
Pregnancy	Geographic location (e.g., East vs. West coast of the United States)
Diabetes	Lower social economic status

SOURCE: Adapted from Table 4-1 of SO_2 Integrated Science Assessment , 2010 (http://cfpub.epa.gov/ncea/cfm/recordisplay.cfm?deid=198843).

between ambient PM levels and increases in cardiopulmonary morbidity and mortality. Age has been consistently shown to influence health outcomes, and the association between ambient air pollution and increases in hospital admissions for asthma is driven by the response seen in children. Conversely, the association between episodic exposure to PM and cardiac mortality is strongest in those over 65 years of age.

Susceptible subpopulations that show exaggerated responsiveness to pollutants merit special mention. The existence of sensitive individuals and groups is well accepted among those who conduct air pollution health assessments, but relatively little is actually known about the host traits that render certain individuals sensitive to inhaled particles and gases. This appreciation for sensitive populations is specifically noted in the CAA, where protection of these groups is mandated in the setting of the NAAQS in the United States. The WHO has a broader definition which encompasses issues that stand out in developing nations as well as those in prosperous countries. They use the term "vulnerability" as the degree to which a population, individual, or organization is unable to anticipate, cope with, resist, and recover from the impacts of disasters (WHO, 2002). There are some definable subgroups that are considered inherently more susceptible or vulnerable to air pollution, including children, the elderly, and those with a preexisting disease (e.g., asthma, cardiovascular disease, and lung disease), but there are other social stressors which also come into play. The importance of susceptibility in air pollutant responses is gaining more and more attention, as test subject responses that were once considered "outliers" in empirical or observational studies may well be evidence of unusual responsiveness.

In some cases, susceptibility may simply reflect differences in dosimetry. Children spend more time outdoors than adults, are more active, and have basal ventilation rates that exceed adults on a volume-to-body weight ratio, and therefore may experience overall greater dose to the lungs. Certainly, rapidly growing tissues may also factor in and may have contributed, perhaps with dosimetry factors, to epidemiology findings showing that polluted urban air retards lung growth (Gauderman et al., 2004). Similarly, adult humans and animals with obstructive airway disease, for example, may have "hotspots" of particle deposition in the airways that exceed normal local tissue doses many-fold (Sweeney et al., 1995; Kim and Kang, 1997). Another often underappreciated aspect of susceptibility relates to the loss of functional reserve or compensation due to age or disease, perhaps altering a response threshold or impairing recovery and the re-establishment of homeostasis. For example, air pollution–induced changes in physiologic measurements such as blood pressure or heart rate may be easily restored in a young healthy individual but not in a more fragile older person with cardiovascular disease.

As already noted, there is also growing interest in gene–environment interactions where genetic differences can influence the responsiveness to environmental stimuli. For example, because the variability in response to ozone was much greater among human subjects than within subjects exposed to ozone in a controlled clinical exposure setting, research in the 1990s suggested that genetic factors influence the response to ozone (McDonnell, 1991). This observation was preceded by an animal study in which significant inter-strain differences were found in inbred mice exposed to high levels of ozone (Goldstein et al., 1973). Since these early studies, human (controlled exposure and epidemiology studies) and animal studies have clearly shown that the response to an inhaled pollutant is dependent on genetics. In humans, the null GSTM1 allele affects about 50% of the population and thus a defect in gene function may undermine antioxidant defenses in those individuals (McCunney, 2005). A number of studies have shown that the null (deletion) GSTM1 genotype, in comparison to the normal wild-type allele, is associated with a greater response to ozone and that the observed pulmonary function changes are even larger if other gene variants involved in oxidative stress are present. Unfortunately, the majority of human studies have examined the contribution of only one or a handful of gene variants at a time. Current state-of-the-art techniques, however, now permit the study of the individual and interactive role of numerous (and someday all) gene polymorphisms in the response to inhaled pollutants. Animal studies have advanced from classical quantitative linkage analysis studies of single sensitive and resistant inbred mouse strains to haplotype mapping studies which take advantage of the complete sequencing or deep single nucleotide polymorphism (SNP) analysis of multiple inbred mouse strains. Similarly, in human studies, we now have the capability to perform genome-wide association (GWA) studies which link up to a million SNPs or haplotypes with a given phenotype/disease in large (i.e., tens of thousands) population studies. Not surprisingly, these GWA studies have determined that individual gene polymorphisms contribute to only a small fraction of the variability in response or disease. Thus, at present, genetic susceptibility, as well as overall susceptibility, to inhaled pollutants is a complex concept that bears significantly on any response. Individual variations in response to ambient air pollution may reflect differences in dose, sensitivity, and/or compensation. As a result, outcomes among individuals may be similar, but the balance of contributing factors that underlie the individual response may be multifactorial.

The study of adverse effects in human volunteers undergoing controlled exposure to air pollutants is ethically limited, but it is even more so for compromised human subjects. Such studies of susceptibility are confined to subjects of only modest suspected risk such as mild asthmatics, healthy older adults, and asymptomatic cardiopulmonary subjects. Inroads have nevertheless been made in recent years because of more thorough prestudy assessments of potential risk factors, allowing researchers to design studies that need not carry undue risk of serious complications. New molecular methods also allow more sensitive assessment of putative biomarkers of response. Additionally, the development of more appropriate animal models of disease or dysfunction (e.g., obese or diabetic mouse models) provides a useful adjunct to explore susceptibility factors more extensively prior to study in humans. Hence, coordinated studies in animals and human subjects are proving to be useful to investigate specific questions such as the roles of pre-existing disease, diet (e.g., antioxidant content), exercise (as it relates to dosimetry), age, gender, and race. The goal of such susceptibility studies is to elucidate patterns, common factors, or pathways that may inform potential intervention or mitigation strategies as well as basic information to reduce the uncertainties regarding risk factors (Kodavanti et al., 1998).

To augment genome studies in humans, recent advances in molecular biology allow the assessment of phenotypic traits in animal models tied to identifiable genes that are homologous to humans. Natural variants in mouse genetics and specially bioengineered transgenic and knockout mouse strains (and in some cases rats) are now widely used to explore the mechanistic basis of phenotypic responses to air pollutants. These new biological tools hold great promise in better understanding responses and establishing gene–environment interactions that may underlie variation in human responsiveness. Transgenic strains can be devised to express desired gene-linked traits using genes inserted from humans as well as other animal models, while knockout models with specific genes removed or silenced can be made devoid of specific traits to isolate responsiveness mechanisms to a toxic challenge. The use of CRISPR/Cas9

technology to target and generate specific mutations in the mouse genome has significantly reduced the time and costs associated with the development of genetically modified mice. These engineered animal models add to the availability of natural mutants that have been inbred historically to "fix" a desired genotype with a specific phenotype expression (Glasser and Nogee, 2006; Shapiro, 2007). Current technology can also target specific genes for isolated expression in the lung (e.g., linked to surfactant protein C), and in some cases controlled by genes which an investigator can switch on or off using a pharmacologic or chemical pre-challenge. These advances allow the dissection of underlying mechanisms under very controlled scenarios and avoid the problems of having a gene inappropriately active or inactive through all life stages or throughout all body tissues.

The use of genetically modified animal models in air pollution research has generally lagged behind that of basic science and toxicology. The reasons for this are likely many, including practicality and expenses, but may relate to the difficulties in incorporating such data into conventional risk-assessment paradigms. However, with recent interest in susceptible groups, there has been a definitive upswing in the use of pharmacologically, naturally altered, or bioengineered animal models to more closely link mechanistic profiles to basic human biology. Ozone has been a common test pollutant in these new studies, because more is known about O_3 and its effects in humans than about any other air pollutant. Frequently, these studies address aspects of inflammation and antioxidant capacity relative to challenge by O_3 and other oxidants (Bauer and Kleeberger, 2010; Groves et al., 2013). But with the current interest in PM health effects, these and other models are being redirected. Examples include strain differences and acid-coated PM (Ohtsuka et al., 2000); atherosclerosis-prone ApoE$^{-/-}$ mice and concentrated ambient PM (Chen et al., 2010). Among rats, the spontaneously hypertensive rat (SHR) and its variants have gained considerable popularity because hypertension is thought to be a human risk factor and because this rat model resembles human hypertension with serum oxidant imbalances, heart disease, as well as its sensitivity to lung injury from inhalants (Kodavanti et al., 2015). The curious are directed to the rapidly evolving literature in this area of research.

EXPOSURE

Air Pollution: Sources and Personal Exposure

Six major air pollutants (PM, O_3, NO_x, SO_2, CO, and Pb) are considered ubiquitous to industrialized communities and are thought to carry the greatest risk to human and environmental health. Except for O_3, these pollutants are emitted by anthropogenic combustion processes along with the myriad of special chemical compounds (mostly volatile organic compound [VOCs]) considered under the category of HAPs. There are many natural sources of air pollutants as well (e.g., volcanoes, wildfires, windblown dust, and natural biogenic vapors), but it is the anthropogenic sources that emit pollutants that concentrate where people live that raise concerns about their potential health impacts. These factors do not dismiss the significance of potential risks posed by the natural emissions but put focus on the potential for human exposure and risk.

Great strides have been made in reducing the emissions of some pollutants. Airborne Pb is down 99% in the United States since it was removed from motor vehicle gasoline in 1973. Similar measures were taken throughout Europe in the 1970s and 1980s. The United Nations Environment Program has been actively advising all countries in the world to use only unleaded gasoline and currently only a small number of countries have not restricted the use of Pb in gasoline. What remains in ambient air emanates from a few isolated stationary sources and re-entrained Pb in road dust. Of the other five criteria pollutants, overall emissions in the United States have been cut 71% since 1970, while at the same time the U.S. Gross Domestic Product (GDP) has increased 246%. Energy consumption has increased 44%, and vehicle miles driven have increased 184% (2014 National Emissions Inventory [NEI] and 2017 Air Pollutant Emissions Trends) (U.S. EPA, 2018). The changing profile of pollutant emissions since 1900 is reflected in Figs. 31-8 and 31-9. From 1980 to 2015, air quality has continued to improve with reductions in ambient SO_2 being largest (−84%) (Table 31-4). O_3, which is formed in the air from emitted precursors of both natural and man-made sources, has changed

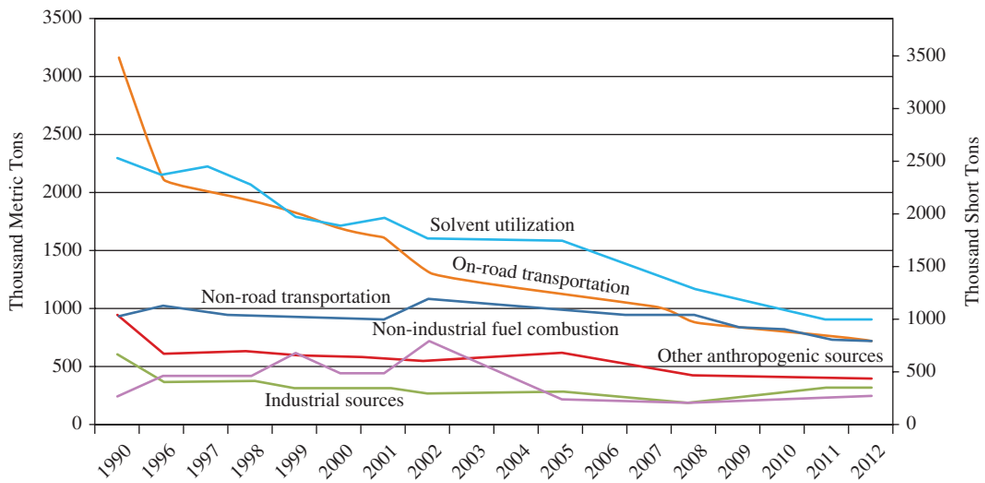

Figure 31-8. *U.S. emission trend for volatile organic compounds (VOC) from 1990 to 2012. From Canada–United States Air Quality Agreement Progress Report 2014.* Modified from Figure 17 of the Report which reports VOC source trends from a defined region in both countries known as the Pollutant Emission Management Area (PEMA), which includes central and southern Ontario, southern Quebec, and 18 U.S. states where emission reductions are most critical for reducing transboundary O_3. Source: Canada–United States, Air Quality Agreement Progress Report 2014. Figure 17.

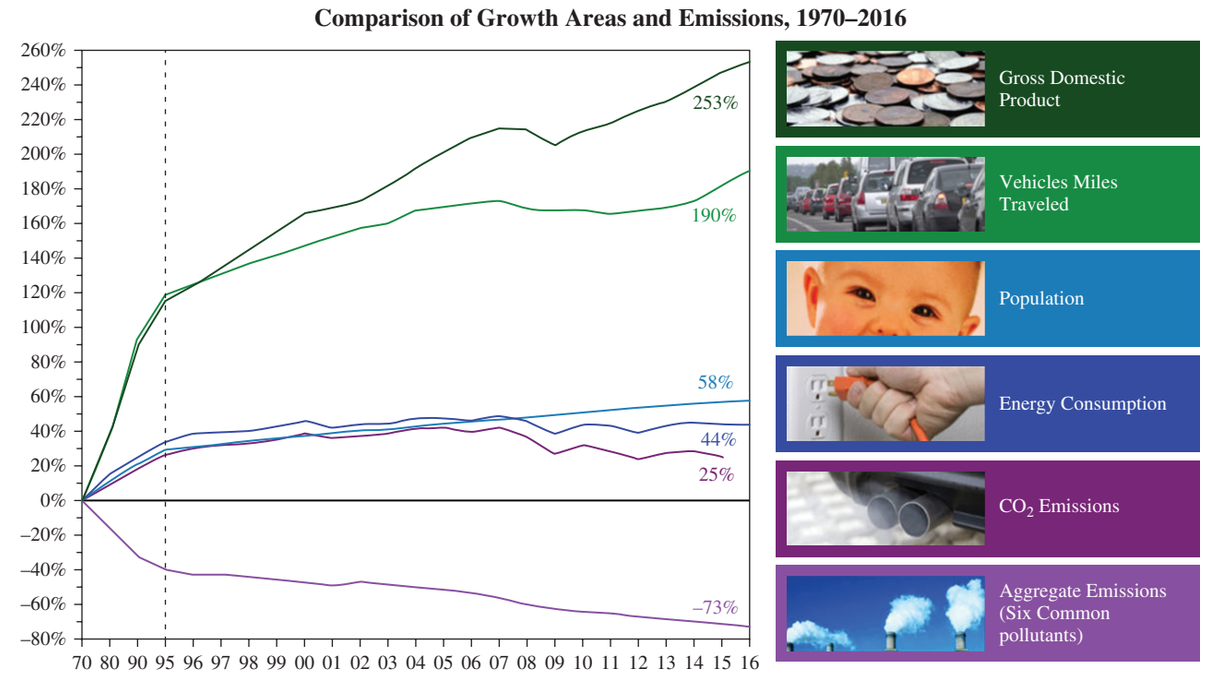

Figure 31-9. *Comparison of growth measures and emissions from 1970 to 2015.* The U.S. population grew by more than 40% during this period. Energy consumption and associated CO_2 levels which historically tracked with population have tailed off in part due to the economic downturn between 2008 and 2012, but these have not rebounded due to conservation activities and alternate energy forces. Meanwhile, miles traveled have doubled and the economy has grown 2.5 times. Yet, the six common criteria air pollutants fell by two-thirds are indicative of great advances in industrial and motor vehicle efficiencies. (From Air Quality—National Summary; U.S. EPA [2016]. Figure used with permission.)

Table 31-4

Air Quality Trends in the United States from 1980 to 2015

POLLUTANT	1980 vs. 2015	1990 vs. 2015	2000 vs. 2015
Carbon monoxide	−84%	−77%	−60%
Lead	−99%	−99%	−91%
Nitrogen dioxide (annual)	−60%	−54%	−45%
Nitrogen dioxide (1-hour)	−59%	−47%	−31%
Ozone (8-hour)	−32%	−22%	−17%
PM_{10} (24-hour)	—	−39%	−36%
$PM_{2.5}$ (annual)	—	—	−37%
$PM_{2.5}$ (24-hour)	—	—	−37%
Sulfur dioxide (1-hour)	−84%	−81%	−69%

Note: The table, listing the % decrease in airborne concentrations of these criteria pollutants across the United States, shows that considerable progress has been made in improving air quality (https://www.epa.gov/air-trends/air-quality-national-summary#Emissions%20Trends).

the least (–32%). Obviously, for any specific locality, air quality can vary depending on the emission profiles of local sources, geographic topography, and meteorology. In the vicinity of a smelter, SO_2, metals, and/or PM, for example, may dominate the pollutant profile, while an oil refinery air shed might be dominated by VOCs and other carbonaceous products. In suburban areas, where the automobile is the main source of pollution, CO, VOCs, and NO_2 would prevail along with their primary photochemical product O_3. NO_x releases (including NO_2) by stationary sources also contribute to the local O_3 levels along with that derived secondarily from auto emissions. Importantly, in 2015 about 121 million people in the United States lived in counties that have violations of the NAAQS designed to minimize risks to the criteria pollutants, whereas in 2014, 92% of the world population resided in places in which WHO air quality guidelines were exceeded.

Assessing exposure to an air pollutant has long rested on observational measures of what is in the air. Indeed, much of epidemiology rests on the principle that what is in the air reflects what an individual is actually exposed to and ultimately inhaled. Exposure science is advancing rapidly and now utilizes approaches that range from novel statistical treatments of traditional exposure metrics to sophisticated models that systematically involve aerodynamic and microenvironmental characteristics to estimate or predict exposures to individuals or populations. The treatment of this subject is well beyond the scope of this chapter (Zou et al., 2009), but the concept is critical to any toxicological evaluation of air pollutants. It also bears heavily on the appropriate approach to conducting inhalation studies in animal models to study air pollutants. Typically, inhalation studies of animals typically involve square-wave exposure patterns, although it is well-appreciated that human exposures vary spatially and temporally. Moreover, animal studies are generally done during the workday (daytime), which is the nocturnal sleep time of most rodent models. In the latter case, one might expect different ventilation patterns in sleeping rodents as compared to humans in their daytime activities and perhaps inverted diurnal

biochemical activities associated with feeding cycles. Such differences may not have significant impacts on animal toxicological results, but the potential for differences needs to be appreciated and respected in translational or interpretational activities.

Indoor versus Outdoor People in the United States (and in most industrialized nations) spend in excess of 80% of their time indoors while at work, school, and home or between these places in an automobile (Robinson and Nelson, 1995). Generally, the time spent indoors is disproportionately higher for adults, who have relatively less time to participate in outdoor activities, especially during the day, when outdoor pollutants are usually at their highest levels. The outdoor activity pattern for children is changing, however, and potentially has consequences such as the increased risk of obesity and other health/growth parameters. Perhaps the most significant risk factor in indoor air for children is the presence of asthma. With an asthma prevalence of nearly 10% in children, the risk of exposure to pollutants and allergens in concentrated form is particularly great.

As to the issue of total exposure, children and outdoor workers are thought to be more likely to encounter outdoor air pollution at its worst; in fact, the relatively high physical activity levels of these subgroups leads to larger doses of any given pollutant being delivered to the lungs. Thus, while it is important to characterize and track pollution levels in outdoor air, a realistic exposure estimate is perhaps best achieved when some indoor/outdoor proportionality can be included as well as some indicator of physical activity. From these data, it would be possible to estimate lung dose, although uncertainties can increase with each increment of personal detail. Defining personal exposure can be extremely difficult, as personal monitoring is tedious, expensive, and can sometimes be confounded by other contributions to the indicator being monitored. Hence, exposure measures are typically drawn from ambient measurements or derived from models developed from studies of groups of people carefully characterized across personal exposure modifiers—exercise, personal lifestyles, etc.

The indoor environment has gained appreciation as a major contributor to total personal exposure. The energy crisis of the 1970s spurred efforts to increase home and building insulation, reduce infiltration of outside air, and minimize energy consumption. At the same time, indoor sources of air contaminants have been on the rise from household products and furnishings, which—when combined with poorly ventilated heating systems and overall reductions in air-exchange rates—give rise to potentially unhealthy indoor air environments. As people begin to notice patterns of odors, microbiologic growth, and even ill health, measures of indoor air become a significant part of environmental risk assessment. Personal exposure has, therefore, come to include the myriad of potential sources, both outdoors and indoors.

It is clear now that indoor air can at times be more complex than outdoor air, a point often raised in challenging the legitimacy of studies that rely solely on outdoor monitoring data. Nevertheless, the national monitoring network for the criteria pollutants has been shown to reflect human exposure reasonably well for some pollutants, especially those that are chemically nonreactive. Indeed, outdoor air permeates the indoor environment despite the reduced air exchange in most buildings. However, many variables determine how well components of the outdoor air infiltrate. The current evidence suggests that the average insulated home has about one air change per hour, resulting in indoor concentrations of pollutants that range from 30% to 80% of that outdoors. For nonreactive gases (e.g., CO), there could likely be nearly a 1:1 indoor/outdoor ratio in the absence of a "sink" for that gas; the ratio for fine PM (less than 2.5 μm) could also be fairly high (approximately 0.4 to 0.7), since these particles can easily penetrate through cracks and open spaces. In contrast, the indoor/outdoor ratio of O_3 is low (less than 0.3) because of its reactivity. Obviously, household differences in the use of window ventilation and air conditioning can also be important variables. Not to be overlooked, of course, are independent indoor sources of contamination where the ratio of an indoor pollutant to that outdoors can even exceed 1 (e.g., NO_2). Particles and gases from tobacco smoke, unvented space heaters, and poorly vented fireplaces and wood stoves as well as fresh paint and cleaning agents can be significant indoor sources. Attention is also being directed toward the many and varied insidious sources of indoor contaminants: certain soils and construction masonry emit radon, gas cooking appliances emit NO_x, sidestream tobacco smoke emits PM, CO, and a host of carcinogenic polyaromatics, and carpets, furnishings, dry-cleaned clothes, and household air fresheners can emit a wide range of VOCs. Responses appear also to be affected by ambient comfort factors such as temperature and humidity. Additionally, some of these chemicals can even interact with one another as has been found to occur with O_3 diffused indoors reacting with VOCs emitted from household cleaners to form small particles. The complexity of these multiple sources underscores the importance of appreciating the total exposure scenario if we are to understand the nature of air pollution and its potential effects on human health (Fig. 31-10).

There remain two broadly defined illnesses that were identified in the 1980s that are largely unique to the indoor building environment (Brooks and Davis, 1992). The first is "Sick-Building Syndrome," which is a collection of ailments defined by a set of persistent symptoms enduring at least 2 weeks (Table 31-5) and appears to occur in at least 20% of those exposed. The pattern is complaints by the building inhabitants, typically of unknown specific etiology sometimes even with ambient measurements, but is relieved sometime after an affected individual leaves the offending building (Hayes et al., 1995). Frequently but not always, this syndrome occurs in new, poorly ventilated, or recently refurbished office buildings. The suspected causes include combustion products, cleaning chemicals, biological emissions from mold, and vapor emissions from furnishings. The perception of irritancy to the eyes, nose, and throat ranks among the predominant symptoms that can become intolerable with repeated exposures. Controlled clinical studies have shown concentration- and duration-dependent worsening of sensory discomfort after exposure to a complex mixture of 22 VOCs commonly found in the indoor environment (Molhave et al., 1986). The many factors contributing to such responses are poorly understood but include various host susceptibility factors such as personal stress and fatigue, diet, and alcohol use. Current biomarkers of response used in the laboratory include sensory irritancy to the eyes in volunteer test subjects and sometimes in animals. However, in general, animal studies using standard measures of sensory irritation or other corporal endpoints have had limited success in assessing sick-building syndromes (SBS) and related syndromes. Human perception factors are believed to be critical to the response patterns.

The second syndrome (building-related illnesses) is a group of illnesses, which in contrast to the SBS, consists of well-documented conditions with defined diagnostic criteria and generally recognizable etiology. These illnesses typically call for conventional medical treatment strategies, since simply exiting the building where the illness was contracted may not readily reverse the symptoms. Several biocontaminant-related illnesses (e.g., Legionnaires disease, hypersensitivity pneumonitis, humidifier fever) fall into this group, as do allergies to animal dander, dust mites, and cockroaches. Medical treatment and mitigation of exposure (source elimination or personal

protection) are generally needed to abate symptoms. Some typical outdoor pollutants can also be problematic indoors—most notably, CO from poorly vented heaters. Indoor exposures to NO_2 can pose problems as well, especially in people who may be sensitive—such as asthmatics. At times, however, when the concentrations of CO, NO_2, and many VOCs (passively emitted from new furniture or rugs, or from mold in the ventilation system) result in less discernible or definable signs and symptoms, the responses may be misdiagnosed as SBS, which can complicate assessment of the situation.

Many inhalants, such as NO_2 and trichloroethylene (a VOC common to the indoor air arising from chlorinated water or dry-cleaned clothes) have been shown in animal toxicology studies to suppress immune defenses and allow opportunistic pathogens to proliferate in the lung. The involvement of immunologic suppression is a particularly controversial, yet important attribute of indoor pollution because of its insidious nature and its implications for all building-related illnesses. This problem is further complicated in that complex indoor environments comprising of chemicals and biologicals (dust mites, fungi, molds, etc.) may also lead to unexpected interactions that, to date, remain virtually unstudied and thus are under-appreciated in the assessment of indoor pollution.

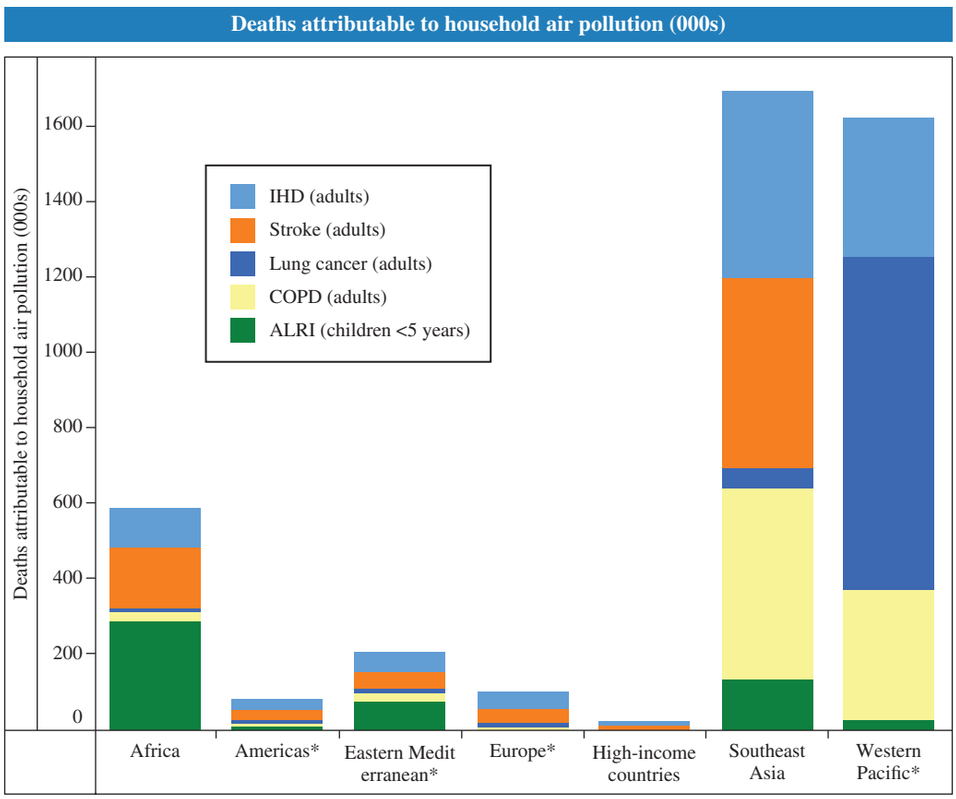
Recently, there have been incidents that highlight indoor air pollution. Post Hurricane Katrina (2005) deployment of trailers where people lived for extended periods resulted in exposure to formaldehyde from urea foam insulation with a myriad of effects on inhabitants—notably children. More recently, wallboard of Chinese origin, which had sulfate and other chemical components on the sealant surface paper that vaporized into the air, resulted in a wide array of symptoms among inhabitants as well as corrosion of some materials. Clearly, the indoor environment is not to be underestimated as to its potential for impact on human health.

Indoor Air in the Developing World Pollution of the indoor environment in the developing world is a major issue; in some parts of the world this issue actually overrides outdoor air pollution. In the more urbanized environments, there is indoor

infiltration of outdoor pollutants unhampered due to poor housing stock. Superimposed on the infiltration of ambient air pollutants are indoor emissions from cooking practices, the cultural use of incense, tobacco, and various other substances, like perfumes. In less developed communities, unvented or poorly vented cookstoves which burn biomass are used much as they have been for centuries. The emissions from these cookstoves, used by approximately 3 billion people worldwide, accumulate indoors exposing families, and especially women and children, to soot and account for 4.3 million premature deaths around the world (Fig. 31-11). Chronic lung diseases, such as bronchitis, emphysema, and cancer, are major killers of exposed women, while children suffer from bronchitis and various other infectious lung diseases. The cookstove issue is the focus of a UN Foundation established in 2010 called the Global Alliance for Clean Cookstoves (UN Foundation, 2010), which is a multinational effort to replace existing dirty stoves with clean culturally practical alternative cooking stoves and devices. The black carbon (soot) emitted from the dirty stoves is also believed to be a major contributor to global climate change.

Evolving Profile of Outdoor Air Pollution Classically, ambient air pollution was distinguished on the basis of the chemical redox nature of its primary components. Dickens's 18th-century "London's particular" referred to a chilled, acrid fog resulting from the accumulation of SO_2 and smoke from incomplete fossil fuel combustion during frequent meteorological inversions. This acidic mix reacts with surfaces, corroding metal, and eroding masonry, characteristic of reductive chemistry. These reducing-type atmospheres have long been associated with smelting and related combustion-based industries (as along the Meuse River in 1930 and Donora, Pennsylvania, in 1948) as well as with large, urban centers (e.g., London in 1952; New York in 1962) burning coal or other dirty fossil fuels for energy. In contrast, Los Angeles has always had a characteristically "oxidant-type" pollution consisting of NO_x and other secondary photochemical oxidants, such as O_3, aldehydes, and electron-hungry hydrocarbon radicals. By virtue of its regional topography and summer meteorology, Los Angeles is particularly prone to trap traffic emissions, while other areas, like Atlanta and regions of India, can be plagued by stagnant, humid summer air.

The classical types of air pollution were implicitly seasonal. Reducing-type air pollution occurred during winter periods of oil and coal combustion used for heating and power coupled with meteorological inversions, while the oxidant atmospheres occurred during the warmer months of spring and summer, when sunlight is most intense and can catalyze reactions among the constituents of auto exhaust. Today the urban distinctions between reducing and oxidant smogs have become largely an academic or historic exercise. Most U.S. urban areas have virtually eliminated smoky, sulfurous emissions (through regulation and a changing national industrial profile) and now with suburban sprawl have a proliferation of automobiles that contribute tons of oxidant precursors into the ambient air. However, in the Midwest there remains still



* Low- and middle-income countries.

Figure 31-11. *Illustration of contribution of burning solid fuels to global mortality by region.* The figure shows considerable region-by-region differences in total deaths that can be attributed to combustion of solid fossil fuels such as wood and other biomass materials. relatively heavy industrial activity that continues to emit SO_2, albeit much less than decades ago, but whose emissions are targeted for further reduction. These emissions continue to have important regional implications as they undergo complex cloud chemistry to form sulfate and impact visibility (regional haze) as well as contribute significantly to PM mass, the primary metric linked to human health effects (Zeger et al., 2006). The air above metropolitan areas in the eastern half of the United States is currently comprised of regional reducing pollutants that distribute and blanket a large segment of the country as well as temporally and spatially varied local source pollutants (HAPs) and secondary oxidant pollutants. Increasingly, oxidants and sulfates formed high in the atmosphere are transported across regions to other locales. In the East, sulfates may still predominate over nitrates in the air, in contrast to the Southwest United States, but nitrates occupy a higher ratio of the pollutant mix than ever due in large part to the growth in traffic and, thus, no longer the Northeastern air pollution is simply a sulfur-based problem. Adding further to the complexity of the ambient air profile is that not only has the composition of the urban haze changed, but the ambient chemistry has affected its temporal patterns. Long extended periods of O_3 (8 to 12 hours) now prevail over wide areas such as southern California and the U.S. Southeast and even along the Northeast corridor. The prototypic spike pattern of an hour or two depicted for Los Angeles in the 1970s, and assumed to be the norm for photochemical processes, has changed. In part, the chemical mixes are different as is the distribution of the sources (motor vehicle traffic). Atmospheric conditions today also seem to promote transport across broad areas affecting background levels. As climate change progresses, there is expectation that the underlying chemistry of O_3 will be promoted further altering these patterns because the assumptions and data that led to current O_3 control measures will be undermined.

Outside the United States, many international megacities remain plagued by the classic reducing and oxidant forms of air pollution. For example, uncontrolled industrial and coal-fired power plant emissions surrounding cities such as Beijing and the northern sectors of Mexico City are dominated by sulfurous, particulate emissions, whereas southern Mexico City, Santiago, and Tokyo have substantially (although not exclusively) automobile-associated oxidant smogs. Impacts on health, visibility, and general welfare are clear and are bringing ever increasing public concern in an all too familiar scenario played out in the United States in the mid-to-late 20th century. Urban air pollution is a worldwide problem, with the attributable yearly mortality for people exposed to O_3 is estimated at 700,000 (Anenberg et al., 2010), whereas PM-related mortality is higher at 3.1 million per year (Lim et al., 2012).

EPIDEMIOLOGIC EVIDENCE OF HEALTH EFFECTS

Outdoor Air Pollution

Acute and Episodic Exposures A number of air pollution incidents have been documented where pollutant concentrations rose to levels that are clearly hazardous to human health. Where a single chemical has been accidentally released (e.g., methyl isocyanate in Bhopal, India), establishing the relationship between cause and ill effect is straightforward. However, most air pollution situations involve complex atmospheres, and establishing a specific cause other than the air pollution incident itself can be difficult. Three acute episodes of community air pollution are considered classic (Meuse Valley, Belgium, 1930; Donora, Pennsylvania, 1948; London, United Kingdom, 1952). In each event, community inhabitants were clearly affected adversely; hospitalizations were concomitant with an elevated mortality rate. Likewise, each involved a meteorological inversion (cold air capped above by a blanket of warm air, with little or no vertical air mixing) that prevailed for 3 to 5 days, during which time the concentration of an array of combustion pollutants rose well above the normal levels for these already heavily polluted areas. No actual measurements of pollution were made in the Meuse Valley and Donora, but crude daily averages of smoke and SO_2 of the London smog incident were recorded—estimated at 4.5 mg/m^3 and 1.34 ppm, respectively, on the worst day. Brief (on the order of hours) peaks of these pollutants certainly were likely much higher. During the Meuse Valley episode, 65 people died, while in Donora the number was 20. These deaths are considered "excess" deaths when compared with normal mortality rates for that time of year that were likely already affected by the background air pollution.

The "London smog" of 1952 was a true disaster with an estimated 4000 excess deaths during the event itself with perhaps thousands more in the weeks to follow. Hospital admissions increased dramatically, mainly among the elderly and those with preexisting cardiac and/or respiratory disease. Even otherwise healthy pedestrians, their visibility limited to as little as 3 ft, covered their noses and mouths in an attempt to minimize their exposure to the acrid air. Many reports of sudden death were reported among workers commuting on bicycle or on foot with symptoms described as "choking." People with preexisting cardiac and lung problems were particularly affected. It is ironic that 16 years earlier, shortly after the Meuse Valley episode, Firkert (1936) predicted that 3200 deaths would occur should a Meuse-like smog strike London. Although the London incident brought the issue of air pollution to the public consciousness, additional episodes occurred with the 1956 and 1962 incidents being among the most notable. But none were of the magnitude seen in 1952. Interestingly, in December 1991, London experienced a winter inversion smog-alert, but one with a very different modern pollutant profile: NO_2 at 423 ppb, black smoke at 148 μg/m^3, and SO_2 at 72 ppb (five, four, and two times the seasonal average, respectively). The differences between this episode and previous episodes were that the air pollution was neither of the magnitude of earlier events nor was it completely dominated by coal emissions as traffic was at this point a major source of oxidant emissions (Anderson, 1999). Overall increases in mortality and hospital admissions were not so apparent, but regional comparisons suggested impacts among the elderly and cardiopulmonary-impaired (mortality: ↑14% cardiovascular and ↑22% respiratory; ↑43% for respiratory admissions). Susceptible individuals are always the first to respond to these pollution episodes, but the impacts eventually are widespread.

During the latter half of the 20th century, other cities experienced notable air pollution events; among these were New York City, Steubenville, Ohio; Pittsburgh, Pennsylvania; Athens, Greece, and major regions of Western Europe from the Netherlands to the Ruhr Valley of Germany. Major episodes of anthropogenic air pollution continue to decrease in the developed world, both in frequency and intensity, but "natural" events like the vegetation/forest fires of Indonesia of 1997 and 1998, greater Moscow in 2009, northern California in 2009 and 2010 all saw significant impacts on wide regional air quality and public health. The impacts of these fires, like that of the U.S. Northwest in 2003, were tracked as their plumes dispersed across the country. Today, the particulate matter generated by wild fires contributes a large fraction of PM in North America, Europe, and Southeast Asia (Faustini et al., 2015; Crippa et al., 2016; Liu et al., 2016). It has been estimated that wild fire emissions can make up as high as 37% of ambient PM (U.S. EPA, 2018a; NWCG Smoke Committee, 2014).

So much had the air cleared in much of the United States from the late 1960s into the 1970s that many thought that the problem of industrial pollution was on its way to full resolution. Smoke from factory chimneys was less visible and the air epidemiology of the times showed little health impact. However, in the 1980s, it was realized that smoky skies were largely due to carbonaceous material and that more efficient burning had eliminated much of what could be seen in the air. But the sulfur in fuel emitted as sulfur dioxide reacted in clouds to form acidic sulfate and traveled great distances depositing and acidifying lakes and streams and at the same time painting the leaves and the ground resulting in defoliation of forests (Calvert et al., 1985). There were also new studies showing that acid haze with O_3 was associated with emergency room visits among susceptible populations—for example, asthmatics (Bates and Sizto, 1987). A series of studies showed acute effects of regional summer haze in areas of Central and Northeastern North America. These 2- to 3-day episodes of haze were typified by increases in O_3 and acid and neutralized (ammonium) sulfates, characteristic of the new generation of pollution in many U.S. urban areas. Interestingly, the apparent combined temporal or sequential patterns of O_3 and sulfate were associated with the health effects, and neither constituent seemed to be acting alone. Similar results were reported for the upstate New York area as well (Thurston et al., 1992), but it seemed the acidity as $[H^+]$ of the haze was the active toxicant. Studies of children at summer camps, where children are active and outdoors most of the day, had reported decrements in daily measured pulmonary function on days of haze when both O_3 and acidity levels were elevated. The responses appeared to exceed those predicted by chamber studies of O_3 alone suggesting dose differences or interactions between haze components (Lippmann, 1989). Clinical studies in adolescent asthmatics and animal studies lent further support to the belief that H^+ can affect airway function, particularly in the presence of O_3. Studies in the South and Southwest similarly found effects in young asthmatics and diminished performance in athletes, but these appeared to relate more specifically to O_3, since sulfate was less prominent in the ambient air of these regions. Yet these epidemiological and field studies showing associations with "acid" haze could not be replicated in the laboratory with either animal or human exposure studies. There could be any number of reasons for this lack of coherence but the exposure concentrations were often orders of magnitude more than in the ambient air. When refined acid measurements in ambient air were used, the consistency of the findings could not be reliably replicated. With no *apparent* impact on mortality in epidemiological studies, the focus of air pollution toxicology focused more and more on O_3 where clinical and animal exposure studies easily could measure impacts on lung function. It was felt that O_3 was the likely culprit and its ubiquity in urban air argued for greater and greater attention. Indeed, many health effects could be ascribed to oxidant/irritant properties of O_3.

Of the many air pollution studies over the last 25 years, none have had more impact on the perception of pollutant risk and the direction of research today than a series of epidemiological studies that showed an association between PM mass concentration (as measured by the regulatory monitoring network in the United States) and daily mortality. These studies departed from conventional epidemiological methods used for air pollution studies in the United States and utilized novel time-series analyses that could more easily blunt the impact of weather, smoking, and other variables that might obscure patterns in health variables linked to the air monitoring data. These studies showed significant and consistent associations between health outcomes of ambient PM at levels previously thought to be safe. Prior to this period, measurable effects of PM and SO_2 were not easily detected below the 24-hour means for smoke and SO_2 250 $\mu g/m^3$ and 0.19 ppm, respectively. In fact, the new findings showed effects, as evidenced by increases in mortality and morbidity rates at or below contemporaneous NAAQS levels (1987: 50 $\mu g/m^3$, annual mean; 150 $\mu g/m^3$ daily maximum for PM of diameter less than 10 μm (PM_{10})). Time-series analyses are based on Poisson regression modeling to distinguish changes in daily death counts (or hospital admissions) associated with short-term changes in air pollution. The studies initially found effects with cruder measures of PM—total suspended particulates (TSP), which includes virtually all particles less than 100 μm in mass median aerodynamic diameter (MMAD—a median particle size normalizing the particle to unit density and spherical shape for aerodynamic comparison). These studies were followed with stronger associations with particles considered almost fully inhalable—PM_{10} (an MMAD at which PM is aerodynamically separated at an initial 50% efficiency at 10 μm and increasingly at smaller sizes). Beginning in the mid-1990s, even stronger associations have been found with an analogous but fully and deeply respirable particle—$PM_{2.5}$. As the PM diameter gets smaller, it better represents anthropogenic sources of pollution. The statistical methodology applied in these time-series studies had an advantage over conventional regression analyses in that it could detect short-term trends and minimize the effects of other pollutants and potential confounders with longer time constants (Schwartz, 1991; reviewed by Pope and Dockery [2006]).

In contrast to the three epidemiologic studies used by the U.S. EPA to develop the 1987 PM_{10} NAAQS, there were more than 30 such studies for the 1997 revision and the promulgation of the new index, $PM_{2.5}$ NAAQS (15 $\mu g/m^3$, annual mean; 65 $\mu g/m^3$ daily maximum for PM of diameter less than 2.5 μm ($PM_{2.5}$)). Today, there are hundreds of corroborating epidemiological studies with those looking at long-term outcomes being of greatest importance. Collectively, these studies show a significant health impact of PM, linked to mass and not necessarily sulfate or any other constituent, although there is some suggestion of prime PM properties. The most consistent attribute is the size—$PM_{2.5}$ appears to be the most generalizable feature in health outcomes. In 2006, the PM NAAQS was revised keeping the annual $PM_{2.5}$ NAAQS at 15 $\mu g/m^3$, with a tightening of the daily maximum to 35 $\mu g/m^3$. The NAAQS for PM is reviewed about every 5 years depending on legal or procedural issues as data accrue; an update on the primary (human) standards for $PM_{2.5}$ (fine PM) and $PM_{2.5–10}$ (coarse PM) is expected in the 2018 timeframe. The PM NAAQS is specifically noted because of all the NAAQS, it has greatest impact on human health of any U.S. regulation both in terms of cost or benefit. As a result, the health science (epidemiology, clinical human exposure and animal toxicology studies) is scrutinized more than any other U.S. regulatory decision.

PM stands as the preeminent air pollutant because of its health impact as well as the pollutant that opened the door to unsuspected targets of injury. The major health outcome revealed in the study of PM has been the involvement of the cardiovascular system as a prime target for adverse impact, and not the lung as historically assumed. While the heart, as part of the cardiopulmonary system, has always held an indirect role in health impacts or disease from air pollution, both epidemiological and toxicological studies now point to major cardiac involvement in PM-associated mortality. Current thinking is that cardiac-mediated effects are more germane to the PM-associated mortality findings than pulmonary effects (Brook et al., 2010). Not surprisingly, effects are most apparent in subpopulations already compromised by cardiopulmonary and perhaps vascular diseases (e.g., diabetes). There exists no one generally accepted mechanism or mode of action to account for these findings (Brook et al., 2010; Cascio, 2016). However, several pathways have been proposed that attempt to link exposure and cardiac effects that may

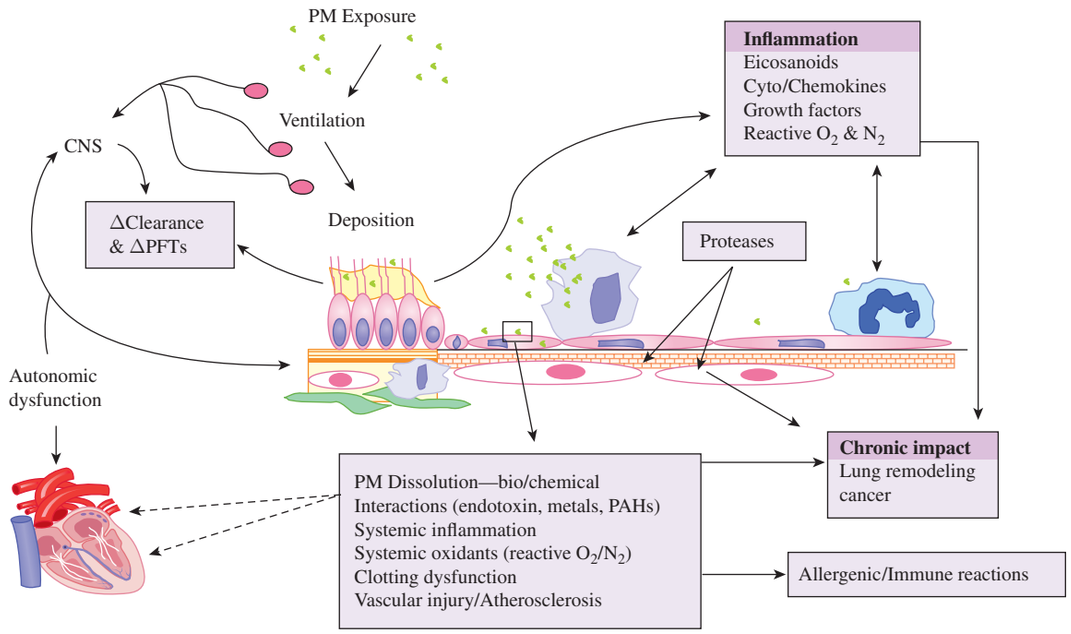

Figure 31-12. *Schematic of the multiple mechanisms thought to function in cardiopulmonary response(s) to air pollutants—derived from current hypothesized mechanisms for particulate matter.*

or may not include pulmonary mediation. These potential mechanisms are illustrated in Fig. 31-12.

From a toxicological perspective, it has been difficult to accept that the association between PM and health outcomes is not somehow linked to particle composition rather than mass alone. The linkage to mass and not composition is counterintuitive, especially in light of the fact that all PM is not constitutively identical. The actual "biochemical lesion" caused by PM is generally thought to involve oxidant mechanisms (generation of reactive oxygen and perhaps nitrogen species) by constituents or attributes (e.g., reactive surface area) of the particles at the cell or molecular level. Initially, there was a credibility hurdle ("biologically plausibility") that day-to-day fluctuations in the mass concentration of about 10 $\mu g/m^3$ airborne PM would result in an increase of about 0.6% to 1% (excess) mortality. However, there now exist several plausible hypotheses that have some degree of empirical support: metals, organics, nanosize with reactive surfaces, and constitutive oxidants to name those most prominent.

The experience with PM has expanded the thinking of the possible extrapulmonary effects of other air pollutants. Potential links to cardiovascular toxicity of several of the NAAQS pollutants have been demonstrated although not with the consistency of PM. Moreover, there are new data showing pollutant-related impacts on birth outcomes, postnatal development, and neurologic health. In the latter case, it is unclear if these effects are related to vascular impacts such as those caused by PM or to other systemic oxidant intermediates.

Long-Term Exposures Epidemiologic studies of the chronic effects of air pollution are difficult to conduct by the very nature of the goal: outcomes associated with long-term exposures. Looking back in time with retrospective, cross-sectional studies was the common approach, but these studies were frequently confounded with unknown variables and inadequate historical exposure data. A good example of the problem of confounding is cigarette smoking. Without extensive information on both active and passive smoking, the ability to discern the impact of an air pollution disease outcome such as chronic bronchitis and emphysema would be greatly impaired. Prospective studies, on the other hand, have the advantage of more precise control of confounding variables, such as the tracking of urinary cotinine as an index of tobacco smoke exposure, but they can be very expensive and require substantial time and dedication on both the part of the investigators as well as the study population. Depending on the study size and design, exposure assessments can be complex, and the loss of subjects due to dropout is sometimes unpredictable.

Despite these deficiencies and problems, there are both retrospective and prospective epidemiology studies that have tackled the issue of long-term air pollution health effects. In general, these studies have suggested a positive association between urban pollution and progressive pulmonary impairments. On the one hand, cross-sectional studies in the Los Angeles Air Basin have found evidence of accelerated "aging-like" loss of lung function in people living for extended periods in regions of high oxidant pollution when compared with areas where sea air circulation lowers overall pollutant concentrations (Detels et al., 1991). Similarly, exposure to SO_2 and PM in the Netherlands over a 12-year period was shown prospectively to gradually impair lung function (Van De Lende et al., 1981). Even rural areas in western Pennsylvania, which are swept by reducing-type pollutants transported from Midwestern industrial centers, have been shown to have a higher incidence of respiratory symptoms as determined from a questionnaire-based design (Schenker et al., 1983). While a negative impact of any specific pollutant followed in these studies is difficult to dissect, the message that long-term exposure to air pollution contributes to deterioration of lung health seems clear.

Among the most detailed prospective epidemiologic studies of chronic health effects across a range of levels of air pollution has been the so-called Harvard Six Cities Study begun in the early 1970s. The cities were chosen to represent a range of air quality based on SO_2 and PM—it was designed as a study of "acid" air

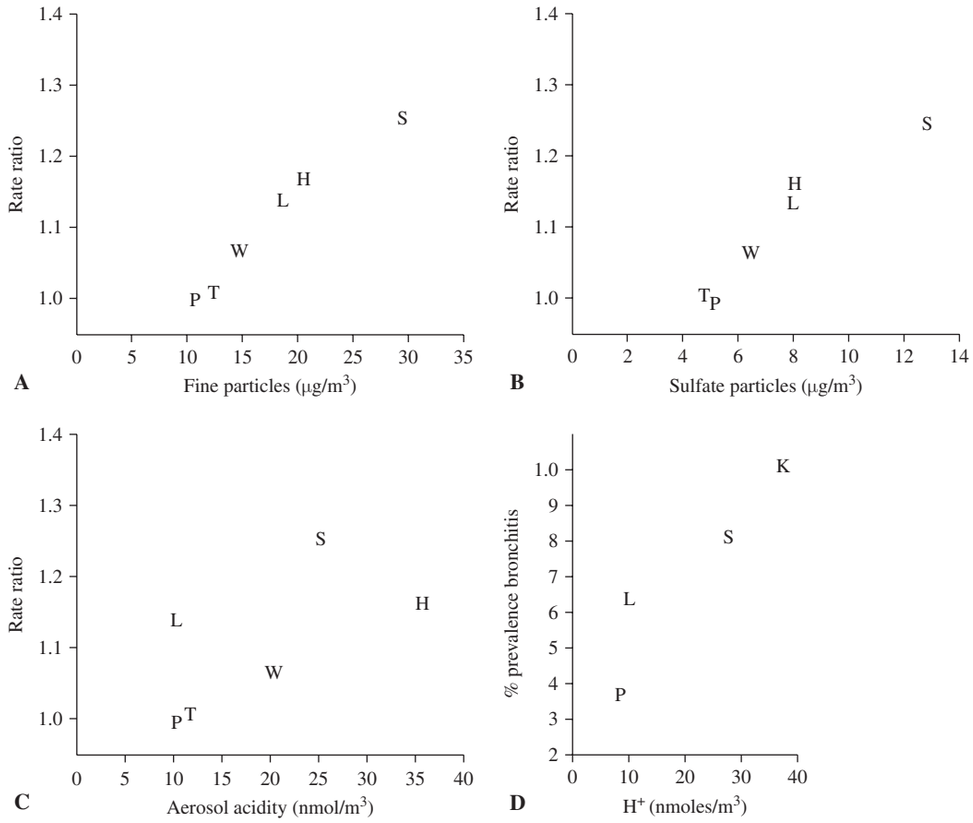

Figure 31-13. *Data from the Harvard Six Cities Studies indicating the superior relationship of PM_{10} and sulfate to mortality rates (**A–C**) in contrast to acidity (**D**), which correlates better with the prevalence of bronchitis in children.* Rate ratio is the mortality rate of each relative to Portage, Wisconsin (P); S = Steubenville, OH; W = Watertown, MA; H = Harriman, TN; L = St. Louis, MO; T = Topeka, KA. (Parts **A** to **C** reproduced with permission from Dockery et al. [1993] and Part **D** reproduced with permission from Speizer [1989].)

pollution. Early on in the study, there was great dependence on routine regional air-monitoring data, but over time the investigators themselves conducted the air analyses of exposure microenvironments (local and indoor). The initial design of these studies included the gathering of parental questionnaire data (including some 20,000 people) about the prevalence of respiratory problems in school children and has continued over 30 years along with periodic assessments of pulmonary function. When compared across cities, $[H^+]$ (measured in four of the six cities) was correlated (Fig. 31-13A) better than was sulfate with the prevalence of bronchitis in children age 10 to 12 (Speizer, 1989). However, as the assessment program evolved, more detailed study revealed mortality associations with PM as represented in Fig. 13B–D. The role of $[H^+]$ in relation with acute mortality was less convincing than that associated with the sulfate or $PM_{2.5}$ (sulfates co-associate with fine PM in the atmosphere) (Dockery et al., 1993). More importantly with regard to long-term health, this study showed very significant effects of PM on the life spans of people living in Steubenville, Ohio—the dirtiest of the industrial centers. Over a 15-year period, the average human life span was reduced by about 2 years due to PM exposure. These findings were corroborated by a prospective cohort-based mortality study using a database collected on over 500,000 people by the American Cancer Society (ACS) across 151 cities from 1982 to 1989 (Pope et al., 1995). The study showed a 15% to 17% increased mortality risk over 7 years due to PM, about equivalent to the risk of smoking over that period. Pope et al. (2002) later reported results of a 10- and again an 18-year follow-up study of the ACS cohort (Pope et al., 2011). Subsequent reports on AARP (Thurston et al., 2016) and large Medicare (Di et al., 2017) cohorts substantiated the earlier findings and demonstrated that cardiovascular effects are observed at very low levels of ambient $PM_{2.5}$. These updated analyses, which included gaseous co-pollutant and new fine-particle measurements, and more comprehensive personal information on the enrollees, confirmed the linkage of health effects, including an increased risk of lung cancer, with $PM_{2.5}$ exposures. These findings reinforce the concerns for potential chronic health impacts of PM and the heightened risk of premature death from lifelong air pollution exposure. Similarly, a study that assessed the health impacts of air pollution in a large multiethnic cohort in North America observed that atherosclerosis and other cardiovascular disease outcomes that might be considered underlying causes of cardiac mortality were significantly associated with long-term exposure to ambient PM (Kaufman et al., 2016).

POLLUTANTS OF OUTDOOR AMBIENT AIR

Classic Reducing-Type Air Pollution

The acute air pollution episodes of the 20th century showed that high concentrations of the reducing-type air pollution, characterized by SO_2 and smoke, are capable of producing dramatic human health effects. Empirical studies in human subjects and animals have long stressed the irritancy of SO_2 and its reaction products in these incidents, while the full potential for interactions among the

co-pollutants in the smoky, sulfurous soup has a mixed record of replication in the human exposure laboratory. Because of its history, SO_2 is often thought of as the prototypic air pollutant of the industrial age, and as such it has a detailed historical literature base. It is an irritant gas that has a toxicology of its own and, through atmospheric reactions, can transform photochemically into sulfites or sulfates as a secondarily irritant particle. The impact of SO_2 emissions on irritancy, the formation of secondary particles that affect visibility, and resultant damaging acidification of the environment have been the drivers of much regulation for coal-fired power plants since 1970. Levels are greatly reduced (more than 80%) in the United States and continue to fall especially after the CAA 1990 and subsequent cross-state regulations.

Sulfur Dioxide

General Toxicology Sulfur dioxide is a water-soluble irritant gas. As such, it is absorbed predominantly in the upper airways. It is a sensory irritant and can stimulate bronchoconstriction and mucus secretion in a number of species, including humans. Early studies with relatively high exposure concentrations of SO_2 showed airway cellular injury and subsequent proliferation of mucus-secreting goblet cells. This attribute of SO_2 led to its use (more than 250 ppm) in the production of laboratory animal models of bronchitis and airway injury (Kodavanti et al., 1998). Chronic exposure studies of experimental animals from mice to monkeys at levels still well-above ambient have yielded qualitative, if variable evidence of airway pathology (Alarie et al., 1970, 1972). Nevertheless, at even lower concentrations (<0.1 ppm), such as might be encountered near an industrial source, long-term residents may experience a higher incidence of bronchitis. Indeed, prior to the breakup of the Soviet Bloc, many eastern European cities were renowned for widespread public affliction with bronchitis; 20 years later, the prevalence of bronchitis was greatly reduced (von Mutius et al., 1994). While other factors (diet, access to health care, other pollutants) may well have been involved in this reversal, reductions in ambient smoke and SO_2 are generally thought to be most important. The concentrations of SO_2 likely to be encountered in the United States continue to decrease and as an annual average are considerably less than 0.01 ppm. As such, not much new SO_2-focused empirical research has been conducted in the past 30 years, but epidemiology has revealed hospitalizations and acute events associated with brief (1 hour) SO_2 spikes (as from stack downdrafts) in exposed sensitive groups.

Contributing to risk is the degree of penetration of SO_2 into the lungs most notable during mouth as compared to nose breathing. Likewise, an increase in the airflow during deep rapid breathing by nose or mouth augments penetration of the gas into the deeper lung. As a result, persons exercising would inhale more SO_2 and, as noted with asthmatics, would be more likely to experience greater irritation. Once deposited along the airway, SO_2 dissolves into surface lining fluid as sulfite or bisulfite and is readily distributed throughout the body and cleared by the kidneys.

Pulmonary Function Effects The basic pulmonary response to inhaled SO_2 is mild bronchoconstriction, which is reflected as a measurable increase in airflow resistance due to narrowing of the airways. Concentration-related increases in resistance have been observed in guinea pigs, dogs, and cats as well as humans consistent with receptor-mediated sensory stimulation. Airflow resistance increased more when the gas was introduced through a tracheal cannula than via the nose, since nasal scrubbing of the water-soluble gas was bypassed. Isolated nasal exposures increased airflow resistance through the nose largely as a result of mucosal swelling, but the irritant effect appeared to signal the more distal airways as well (Frank and Speizer, 1965; Nadel et al., 1965). Intravenous injection of atropine (a parasympathetic receptor blocker) or cooling of the cervical vagal nerves abolishes bronchoconstriction in the cat model; rewarming of the nerve reestablishes the response. The rapidity of the response and its reversal nature emphasize the parasympathetic tonal change in airway smooth muscle. Studies in human subjects have confirmed the predominance of parasympathetic mediation, but histamine from inflammatory cells may play a secondary role in the bronchoconstrictive responses of asthmatics to inhaled SO_2 (Koenig et al., 1981; Sheppard et al., 1981), which raises health concern about this subpopulation when exposure is near point sources.

Chronic Effects Only a few long-term studies have been conducted with SO_2 at levels approaching those found in ambient air and these studies were conducted long ago (Alarie et al., 1970, 1972). Few effects were found other than mild mucosal changes. High levels of SO_2 (200 to 350 ppm for 30 days or more) have altered airway mucus secretion, goblet cell topography, and lung function and have served as a means of developing animal models of bronchitis, but are of little relevance to ambient exposure (Reid, 1963; Lewis et al., 1969).

Sulfuric Acid and Related Sulfates

In the United States, sulfate remains the predominant component of most PM east of the Mississippi River. Its health effects are puzzling in that, as discussed below, alone it seems to have less impact than might be anticipated. However, it may well work in concert with other components of PM to elicit effects; nevertheless, because of its prominence, it merits attention as a classic pollutant that despite all the studies remains a potential contributor to the comprehensive health outcome of exposure to PM.

The conversion of SO_2 to sulfate is favored in the environment with subsequent ammonia neutralization to ammonium sulfate $[(NH_4)_2SO_4]$ or ammonium bisulfate $[NH_4HSO_4]$. During oil and coal combustion or the smelting of metal ores, sulfuric acid condenses downstream of the combustion processes with available metal ions and water vapor or in smoke plumes to form submicron sulfuric acid fume and sulfated fly ash. Further, photochemical reactions also promote acid sulfate formation via both metal-dependent and independent mechanisms in clouds. Although the fine-particle sulfates may exist as sulfuric acid (the primary source of free H^+), partially or fully neutralized forms of sulfate predominate due to the abundance of natural atmospheric ammonia. As fine PM sulfates are transported long distances, they may contribute to regional summer haze and pose a health hazard to certain groups such as asthmatics (Koenig et al., 1989), and may also stress the general environment as acid rain (Calvert et al., 1985) (Fig. 31-14). The reduction of sulfur emissions since the CAA and subsequent regulations (e.g., the 1990 Acid Rain Program and the 2012 Cross State Air Pollution Rule) continue to reduce the environmental acidification and visibility problems associated with transport and deposition of acidic products formed from stack emissions in North America.

General Toxicology Sulfuric acid irritates by virtue of its ability to protonate (H^+) receptor ligands and other biomolecules. This action can either directly damage membranes or activate sensory reflexes that initiate inflammation. Ammonia, which exists in free air at about 25 ppb and in much higher concentrations within the mammalian naso-oropharynx (in the human up to 350 ppm), is capable of neutralizing most of the inhaled irritant acidic sulfates (Utell et al., 1989). Neutralization can also be quite efficient in standard whole-body animal exposure-studies, in which excreta and bacteria in the chambers interact, giving rise to in-chamber

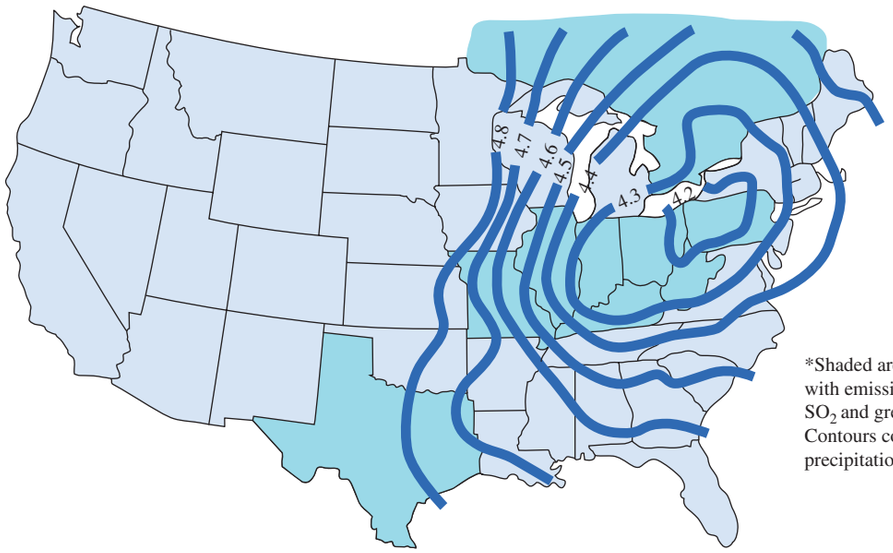

Figure 31-14. *Areas in 1988 where precipitation in the east fell below pH 5: acid rain.* The acidity of the air in the east is thought to result from air mass transport of fine sulfated particulate matter from the industrial centers of the Midwest. (From U.S. EPA [2000].)

ammonia concentrations up to 1100 ppb—more than enough to fully neutralize sulfuric acid droplets up to several mg/m^3 (Higuchi and Davies, 1993).

Interestingly, there is considerable species variability in sensitivity to sulfuric acid, with guinea pigs being quite responsive to acid sulfates, in contrast to rats which seem generally resistant. The reasons for this difference relate to sensory fiber network density in the airways, and probably not on differences in neutralization by ammonia in the airway. The sensitivity of healthy humans appears to fall somewhere in between, with asthmatic humans being perhaps best modeled by the guinea pig. Overall, however, the collective data involving animals and humans are remarkably coherent (Amdur, 1989).

Unlike other irritants, such as O_3, inhaled sulfuric acid does not appear to stimulate a classic neutrophilic lung inflammation. Rather, eicosanoid homeostasis appears to be disturbed resulting in macrophage dysfunction and altered host defense.

Pulmonary Function Effects Sulfuric acid, like SO_2, produces an increase in flow resistance in guinea pigs due to reflex airway narrowing, or bronchoconstriction. Responsiveness to sulfuric acid is both species- (as noted above) and particle size–dependent. In guinea pigs, large particles induce upper airway narrowing and increased resistance. Some human asthmatics can have similar responses in a fog. But typically, only very high "mg" concentrations induce these effects thought largely due to the neutralization of acidity by ammonia. Because of the predominantly neutralized form of sulfate in the atmosphere, sulfates have been largely thought not to be primary or singular bad-actors in air pollution incidents unless at very high concentrations—for example, London Smog (Amdur et al., 1978; Utell et al., 1984; Hackney et al., 1989; Koenig et al., 1989; Costa and Schlegele, 1998). The variability in asthmatics may well relate to differences in the degree of impairment or underlying inflammation in the subjects as has been shown in some animal models, but this hypothesis remains to be confirmed.

Effects on Mucociliary Clearance and Macrophage Function Sulfuric acid does alter the clearance of particles from the lung. Using insoluble, radioactively labeled ferric oxide particles as a probe exposure in donkeys, rabbits, and human subjects show impaired clearance after a single 1-hour exposure (Schlesinger, 1984). Curiously, there appears to be a biphasic response to acid. In general, brief, single exposures of less than 250 μg/m^3 accelerate clearance, while high concentrations of more than 1000 μg/m^3 clearly depress clearance. With repeated daily exposures to low levels, there appears to be a cumulative (concentration times duration) dose-related depression of clearance. Longer-term exposure of rabbits to low-level acid also results in hyperplasia of airway mucosecretory cells (Gearhart and Schlesinger, 1989).

Collectively, there seems to be coherence in the data to rank sulfate irritancy: sulfuric acid > ammonium bisulfate > ammonium sulfate. Acidity [H^+] appears to be the primary driver on most respiratory effects. Nevertheless, in the complexity of summer haze, it remains unclear whether the bioactive form of H^+ is more appropriately assayed as free ion concentration (as pH) or as total available ion concentration (titratable H^+).

Chronic Effects As a fine aerosol, sulfuric acid deposits deeper along the respiratory tract, and its high specific acidity imparts greater effect on various cells (e.g., phagocytes and epithelial cells). As noted earlier, the primary concern with regard to chronic inhalation of acidic aerosols is the potential for bronchitis, because this has been a problem in occupational settings in which employees are exposed to sulfuric acid mists (e.g., battery plants). Studies in several animal models raise these concerns as cigarette smoke shows parallel responses. Related studies suggest that the airways of exposed animals become progressively more sensitive to challenge with acetylcholine, show a progressive decrease in diameter, and experience an increase in the number of secretory cells, especially in the smaller airways (Schlesinger et al., 1992). While highly variable, the possibility that chronic irritancy by inhaled sulfuric acid may elicit bronchitis-like disease in susceptible individuals (perhaps over a lifetime or in children as noted in the Six Cities Study) appears to be reasonable.

Particulate Matter

Particulate matter (PM) was referred to as "soot" in the "reducing-type" air pollution of the classic episodes. The major constituents of this soot consisted of incompletely burned carbonaceous materials,

acid sulfates, various metals, and silicates associated with the solid nature of the fuel. Metal compounds were abundant, with a considerable amount of zinc in the form of zinc sulfate—as reported from post-episode analyses of the Donora PM. Soot is indicative of poorly (inefficiently) combusted fuel. Over time, combustion technology and improved fuels provided gains by increasing efficiency and minimization of gross soot emissions. Improvements in combustion methods simultaneously reduced the size of emitted particles and overall less mass. A side benefit of the smaller particles was the reduction in light diffraction through the emissions and hence a less visible plume. As such, much of the early cleanup was largely achieved through technological improvements. Carbon in fuel that is not fully oxidized to CO_2 persists as black carbon which typically is a mix of the elemental form with variable products of incomplete combustion—organic carbon. Oxidized sulfur becomes sulfate and many of the metals appear as oxides. As noted above, sulfate was long suspected as the essential culprit of most health impacts associated with stationary sources, but this relationship is less discernable in contemporary particle epidemiology and has no good evidence for adverse health effects at reasonable concentrations in either human or animal toxicology studies.

In the last 20 years, PM has reemerged as the dominant societal issue in air pollution, overtaking O_3 as the impact leader in health outcomes. Not that O_3 is of minimal concern, but emergent epidemiology data consistently showed increased mortality, the adverse effect of greatest import having a major societal impact when viewed through cost/benefit analyses. As already noted, the collective studies showed health impacts (both morbidity and mortality) at levels of PM thought to be "safe" with no apparent threshold (reviewed in Pope and Dockery [2006]). Over time, science advances and re-analyses have confirmed the initial mortality findings (U.S. EPA, 2009). In the United States, studies show that even with great reductions in PM, $PM_{2.5}$ still accounts for about 5% of the total mortality burden; indeed, the World Health Organization estimates that PM accounts for up to 7 million deaths a year worldwide. In the latter case, the deaths may be associated with incomplete combustion emissions from domestic burning of biomass.

Several hypotheses lend "biologic plausibility" to the findings and have been linked to an array of effects that have modes of action coherent with potential mortality. The impacts of PM on health have eventually been appreciated to be more systemic than originally thought, beyond the lung as the primary target organ. Significant impacts on the cardiovascular system have emerged and are now generally believed to be the predominant driver of air pollution–related mortality outcomes. Further, there is an ever growing body of data suggesting impacts on neurologic and reproductive health, as well as the more expected impact on the lung—especially in children where chronically PM appears to impact lung growth and development (Gauderman et al., 2015).

Particulate matter in the atmosphere can be solid, liquid, or a combination of both with a mélange of variably combusted or photochemically derived organic compounds coexistent with inorganic species and biological materials or associated compounds. The compositional matrix of PM can vary significantly over time and regionally likely due to varied emission sources and secondary transformations in the atmosphere, which are weather mediated. Long-range transport of emissions or transformation products include sulfates from the oxidation of sulfur in fossil fuel emissions and complex organic compounds called secondary organic aerosols (SOA). Hence, these components comprise the regional matrix of PM, particularly in the case of sulfate in East Coast $PM_{2.5}$. Particles in urban centers, notably in the Western United States, have SOA as the prime component. Particles of larger size (PM_{10}) tend to have more local sources being that they are formed from dispersed dust and attrition of materials. Being of greater mass, the larger particles tend to "fall out" or settle from the air due to gravity (although winds can in fact carry these particles great distances—e.g., Sahara desert particles have been found on the U.S. East Coast). Particles in the range of 10 to 2.5 μm ($PM_{10–2.5}$—coarse PM) are highly inhalable by humans but tend to deposit in the upper airways again due to their mass. In urban settings throughout the world, there is considerable spatial and temporal heterogeneity of coarse PM while $PM_{2.5}$ appears somewhat more homogenous throughout a regional air shed. The size designation of fine and coarse PM is based on their relative respirability—those in the range of PM_{10} are inhalable and deposit in the nasal cavity and larger thoracic airways while the $PM_{2.5}$ is respirable and deposits in the deeper reaches (small airways and gas exchange areas) of the lung (see Chap. 15, "Toxic Responses of the Respiratory System").

The foundational epidemiologic database contending that PM elicits both short- and long-term health effects is largely founded on data from monitoring networks used for PM regulation in North America and Europe. As such, the PM-associated effects appear to be dependent on the gravimetric measures that these networks yield. From this, it might then be argued that the effects are not influenced by particle composition (e.g., inorganic and organic components). Further, because the strength of the impacts increases with decreasing particle size (e.g., total suspended particulate mass [pre-1978 index], PM_{10}, $PM_{2.5}$), it appears that it is the mass concentration of PM, despite compositional complexity and variation, that is the index of choice. However, toxicologists argue that a mass-based relationship contradicts the basic tenets of conventional air pollution toxicology, which is rooted in the concept of chemical-specific toxicities. That is certainly born out with exposures due to proximity to specific sources (e.g., a smelter or coke oven), but oddly data continue to show mass as a primary driver. On the other hand, source apportionment studies strongly suggest, at least epidemiologically, that particular PM sources, such as coal-fired power plants and high volume traffic, contribute to a greater share of the adverse health outcomes and toxicological studies from airsheds of varied compositional character provide refinement in the nature and causation of adversity. The mass driver which encompasses components and interactions among them seems at this point the exposure metric for mortality.

A number of hypotheses that draw upon various physical and chemical attributes of PM have also been offered in search of a "biologically plausible" explanation for the reported epidemiologic observations. However, no one constituent has been identified as singularly determinant of the spectrum of health impacts. The smallest particles, which derive from anthropogenic combustion activities, appear to drive many of the health effects of particles. Prominently included among the causative hypotheses that tie toxicity to particle characteristics are metals, organics, acidity, size distribution (focusing on the potentially unique bioactivity of ultrafine PM—PM less than 0.1 μm), PM oxidant activity or reactivity, and the presence of potentially toxic or allergenic biologicals. However, at present, there remains insufficient understanding of the relative importance of these theories to choose one over another, especially if the spectrum of health effects is included. As a result, there seems to be insufficient reason to unseat the PM mass-based correlation with health outcomes as the driver of regulatory policies. Although the animal and human toxicological database is growing rapidly with regard to the issue of causation, much remains to be learned before new regulatory indices can be considered.

From research directed initially toward potential occupational hazards, it is known that several metals and silicates that make up much of the inorganic phase of PM can be cytotoxic to lung cells. Organic constituents associated with black carbon, as well, can

induce toxicity either directly or via metabolism products—some of which are genotoxic. Other PM attributes may also come into play. Studies focusing on very small, ultrafine particles suggest that although these particles are low in mass, they are high in number and thus provide substantial reactive particle surface to interact with biological substances or that they can more easily penetrate through the lung surface and impart their effects systemically. Less is known about the role of biologically derived ambient materials, such as endotoxin, glucans, plant glycoproteins, and bioallergen fragments, which may elicit rudimentary inflammatory responses in the lung. The involvement of biologicals may be greatest in agricultural and indoor exposure environments. There has been considerable interest in PM–co-pollutant interactions, but our knowledge in this area is somewhat limited and has spurred toxicologists to better access the experience and knowledge of atmospheric scientists as to the atmospheric interactions that are most relevant to biologic outcomes.

Metals There have been many conventional acute and chronic rodent inhalation studies conducted with specific metal compounds, often as oxides, chlorides, or sulfates. The varied toxicological effects of metal compounds are presented in detail in Chap. 23, "Toxic Effects of Metals." However, it should be appreciated that the effects of metals delivered by inhalation may differ from their impacts when administered by other routes and as such inhalation exposures perhaps best relate to occupational exposures. Metals may arise from natural as well as anthropogenic activities, and as a result metals are a common constituent in ambient PM. The PM metal profiles vary geographically and by contributing sources; hence, they can differ appreciably in concentration and type and the size mode in which they occur. Coarse $PM_{10-2.5}$ arises largely from natural sources and thus has prominent earthen metals such as iron, sodium, silica, and magnesium—usually in geologically stable oxide forms. On the other hand, fine ($PM_{2.5}$) and ultrafine ($PM_{0.1}$) are richer in combustion-derived metals, often reflecting the fuel source and nature of combustion. For example, diesel fuel may have vanadium, nickel, and perhaps zinc and iron, while coal may have zinc and selenium. Their chemical forms vary from water-soluble metal salts and sulfates to oxide and phosphate forms. High temperatures and efficient combustion frequently take metals to their smallest size and most oxidized form—the oxides. Metals are also emitted from vehicles burning fuels to which metal compounds were added to alter functionality (e.g., lead, manganese, and platinum) or as engine wear and catalyst by-products. Similarly, metals may also be derived not from combustion processes but from brake (copper, iron), tire (zinc), and road (earthen silicates or dust re-dispersion) wear—again in the larger coarse mode. Metals have many biologic properties, some essential to life while others can be directly toxic to cells or act indirectly as pro-oxidants. Thus, metals have garnered considerable interest regarding their potential role in PM toxicity (Costa and Dreher, 1997).

Metal compounds can be separated nominally by physicochemical characteristics: those that are essentially water-insoluble (e.g., metal oxides and hydroxides such as those that might be released from high-temperature combustion sources or derived from the geocrustal matrix) and those that are soluble or somewhat soluble in water (often chlorides or sulfates such as those that might form under acidic conditions in a smoke plume or leach from acid-hydrated silicate particles in the atmosphere). Solubility appears to play a role in the toxicity of many inhaled ambient-PM associated metals by enhancing metal bioavailability (e.g., nickel from nickel chloride versus nickel oxide), but insolubility also can be a critical factor in determining toxicity by increasing pulmonary residence time within the lung (e.g., insoluble cadmium oxide versus soluble cadmium chloride). Moreover, some metals, either in their soluble forms or when partially coordinated on the surface of silicate or bioorganic materials, can promote electron transfer to form reactive oxidants (Fenton chemistry). Complexes with particulate organic material in a partially hydrated form (as might be promoted by the presence of sea salt) have been shown to interact with poorly soluble metals to free coordination sites to yield pro-oxidant activity (Kieber et al., 2005). Thus, caution is warranted in assessing inhaled PM-associated metals simply on the basis of their chemical form and concentration, as both their chemical and physical attributes and their potential interactions with co-contaminants in PM may influence their ultimate toxicity. Simply measuring total metal mass to estimate adverse effects in the lung can be misleading.

Perhaps the most compelling evidence for a role of soluble metals in PM toxicity derives from a series of U.S. studies on PM sampled in Utah Valley where a large open hearth steel mill went from full production to a 1 year hiatus due to a labor strike and then resumed its open hearth operations. These studies related the metal content of PM sampled in the air surrounding the plant showing a substantial reduction in total PM as well as a reduction in its usual PM metal content during the strike period. Studies of hospital admissions for a variety of lung ailments and death rates showed reductions during the steel mill hiatus in operations which were mirrored in toxicological studies where PM extractions from the operational and shutdown periods were tested in human and animal lungs, as well as on human lung epithelial cells. All studies showed adverse effect correlations with plant operations and PM metal content (Pope, 1996; Dye et al., 2001; Ghio, 2004).

Gas–Particle Interactions As already noted, gas–particle interactions can be extremely complex involving multiple components of the particles, gases/vapors, and sunlight. While most of this chemistry occurs in the air, more than 50 years ago, generic binary interactions between particles and gases, in the absence of light, were shown to alter the toxicity of either the particle or the gas compared to acting alone. The guinea pig bronchoconstriction model used for many years by Amdur and associates showed early-on that SO_2 can interact with hydrated metal salts to potentiate particle irritancy. The mechanism(s) behind this interaction has yet to be fully discerned, but it appears to involve solubility of SO_2 in a hydrated aerosol and the ability of the metal to catalyze the oxidation of the dissolved SO_2 to sulfate during inhalation. In the case of a sodium chloride aerosol, potentiation appeared to be governed primarily by the solubility of SO_2 in the salt droplet and enhanced respiratory penetration. The metal salts of manganese, iron, and vanadium, however, were shown to rapidly catalyze the formation of acid sulfate that could then be quantified in the aerosol, and mediated the irritancy in the bioassay. Interestingly, similar studies in humans have been less revealing about such interactions and their toxic expression, but this in vivo bioassay database affirms the need to consider the complexity of the atmospheric challenge in estimating biological outcomes.

Complex chemistry also occurs within the effluent of the combustion source. Using a laboratory scaled furnace, the emission mix of sulfuric acid and metal oxide particles common to metal smelting and coal combustion was used to explore potential plume interactions that might impact respiratory irritancy (Amdur et al., 1986). These emitted metal oxide particles, once aged and cooled, were a mixture of respirable singlet and agglomerated ultrafine particles. Exposure of guinea pigs to 30 to 60 $\mu g/m^3$ sulfuric acid combined with ultrafine zinc oxide produced progressive decreases in the diffusing capacity for CO (DL_{CO}), total lung capacity, and vital capacity and increases in cells, protein, and a variety of enzymes in lavage fluid that were not completely resolved 96 hours after exposure (Amdur, 1989). It is unclear whether the acid was on the surface

of the particles or made the metal more soluble, but the combination was clearly more toxic than acid alone. Recently, atmospheric studies have suggested that acid sulfate may contribute to the dissolution of metals from particles and make them bioavailable for effects. This could show a role for sulfuric acid that is beyond its apparent minimal intrinsic impacts on the lung—except perhaps in some asthmatics.

Combustion studies using different coals again emphasized the significance of surface-associated acidic *S*-compounds. Ultrafine combustion particles from Illinois No. 6 coal had a layer of sulfuric acid adsorbed on the surfaces resulting in greater effects in guinea pigs than the more alkaline Montana lignite. Despite the greater sulfur content of the Montana coal, this alkaline ultrafine particle had neutralized the irritating sulfate (Chen et al., 1990). Similar studies using inert carbon black appear consistent with its role as carrier for reactive gases or reactive products of the interactions with pollutants such as O_3 and various aldehydes, perhaps enhancing delivery of toxic materials to the deep lung (Jakab, 1992). The result of the latter study was enhanced infectivity when the carbon + gas pre-exposed test animals were subsequently exposed to pathologic bacteria.

Similar interactions may result from gaseous pollutants that impair the clearance of particles from the lung or otherwise alter their metabolism. Studies by Laskin at New York University in the 1960s showed an intriguing interaction of SO_2 and benzo(*a*)pyrene. It was thought that impaired clearance and greater residence time in the lung led to the enhanced probability of carcinogenic potential of the particle. Similarly, rats exposed to an urban 8-hour daily profile of O_3 for 6 weeks, followed by a single exposure to asbestos, were found to retain three times as many fibers deep in the lung 30 days after exposure. The fibers were deposited in the distal airways and penetrated more deeply into airway tissues making them less accessible to phagocytic removal (Pinkerton et al., 1989). These studies, together with those focusing on irritancy and infectivity, raise the prospect that realistic exposure scenarios of gaseous and particulate pollutants can interact through either chemical or physiologic mechanisms to enhance health risks of complex polluted atmospheres.

Ultrafine Carbonaceous Matter Ultrafine ambient carbon particles (often called black or elemental carbon) are emitted during combustion and can mix with less well combusted carbonaceous material (sometimes called brown carbon or particles of incomplete combustion [PICs]) or may occur in a fairly pure form from high-temperature pyrolysis. Black carbon, an older term, is measured differently from elemental carbon, but both are highly correlated and often the terms are used interchangeably. The size of these particles allows them to slip (Brownian motion) between gas molecules moving primarily by diffusion. Agglomeration among themselves, on surfaces, or with larger particles in the air is their primary mode of dissipation. When concentrations exceed about a million particles per cubic centimeters, they rapidly agglomerate with each other to form larger clumps or chains of ultrafine particles. These agglomerates are typified by diesel exhaust particles in the air. As an air pollutant, therefore, elemental carbon particles generally do not exist as singlets except near their emission points—for example, traffic or other high temperature sources. Fine PM consist in part of agglomerates of these and other carbonaceous organic material (brown carbon or products of photo-oxidation known as secondary transformation), which if partially oxidized are variably (though mostly not) soluble in water. Some organic materials which exist in the vapor form may also condense on ultrafine black carbon (e.g., diesel PM).

Estimates of the carbonaceous (including organic) content of ambient fine PM vary considerably but are nominally considered to be about 10% to 60% of the total PM mass depending on the urban or regional area. The sources of organic carbon are varied and include the combustion products of natural smoke (e.g., forest fires), engine exhaust, and stationary sources (even fast-food exhaust emissions). Where there is a strong solar energy source, transformed condensates from volatile organic compounds (VOCs) in the air also can contribute substantially to PM mass. It has been estimated that diesel exhaust contributes about 7% of the primary fine urban PM load, but estimates in urban canyons vary widely. The higher use of diesel fuel for transportation in Europe and areas of concentrated trucking in the United States have led to estimates as high as 30% of local ambient fine PM mass. Elemental carbon has traditionally been associated with traffic. In the United States, black carbon is considered a better marker of older and off-road vehicles, but as new engine technology has emerged in 2007 and 2010 for diesels to meet new emission standards, black carbon emissions are substantially less (less than 99%). New automobiles also emit less black carbon as technology transfers to these vehicles. The expected result over the next 20 years, with the turnover of diesel-powered truck fleets in particular, is a great reduction in ambient levels of black carbon with California already showing these reductions as early adopters of the new technology.

Diesel exhaust particles vary widely in the ratio of organic and elemental carbonaceous materials, which in empirical studies has been shown to influence toxic outcomes, such as their inflammatory and carcinogenic potential (Singh et al., 2004; HEI, 2015a, 2015b). Some diesel particles also appear to have adjuvant activity when tested with bioallergens in both animals and humans (Diaz-Sanchez et al., 1999). When reacted in vitro with O_3, there appears to be an enhancement of lung inflammation relative to the diesel or O_3 alone (Madden et al., 2000). However, it is important to realize that diesel particles should not be equated with whole diesel exhaust that also contains significant amounts of gaseous pollutants: NO_x, CO, and SO_x as well as various VOCs and carbonyl irritants. Exposure to diluted diesel exhaust in humans reveals that the exhaust mix is inflammogenic in the lung (Salvi et al., 2000) and to a degree cytotoxic to airway cells (Ghio et al., 2012). The use of diesel particles alone in toxicology studies does not seem to display similar toxicity to the total exhaust, thus underscoring the potential importance of interactions among air pollutants as a critical consideration in air pollution toxicity (Mauderly and Samet, 2009).

Recent epidemiological and field studies with PM have focused on black or elemental carbon as an index of traffic and reported strong associations between traffic (through the carbon indicator) and adverse health effects. Ultrafine particles in the near-traffic environment exist in extremely high numbers but contribute negligibly to mass, the metric which has proven to be most credible to date. However, the predominance of cardiovascular associations gives some credence to a hypothesis that ultrafine particles somehow find their way into the systemic circulation and/or trigger systemic inflammation that links to the cardiovascular effects (Peters, 2006; Tong et al., 2010). The ultrafine mode of black carbon has been suggested to be more toxic than fine-mode $PM_{2.5}$, perhaps due to enhanced surface reactivity or co-pollutant carrying capacity as noted above, but tissue penetration (Donaldson et al., 1998; Oberdorster et al., 2002) has emerged as a hypothesis as well. The penetration of ultrafine particles from the lung into the circulation under experimental conditions has been reported, but appears to be composition dependent (Kreyling et al., 2009); this unique potential of ultrafines to act through systemic penetration is intriguing but remains to be shown as a major contributing factor to ambient PM toxicity.

Pure elemental carbon itself is generally considered to be of low toxicity, although long-term, high-concentration exposure conditions in rats can lead to lung "overload" where there is evidence of lung damage and carcinogenicity. Recent commercial introduction

of "engineered" nanoparticles brings many of the same concerns as ultrafines by virtue of their similar sizes. Additionally, being "engineered" particles, they may possess design features that "natural" combustion ultrafine (or nano) particles do not.

Internationally, the impact of black carbon remains complex as many of the older transportation and trucking vehicles being replaced are sold to the developing world so their contribution to global emissions will not fall as rapidly. Moreover, the use of two-cycle engines and the domestic combustion of biomass in the rural developing world will continue to contribute greatly to the global load and health impact of black carbon and PM. Not fully appreciated as an indirect impact of black carbon to air-related adverse health is via the impact of black carbon on climate. Black carbon from developing world, as well as older industrial world, sources undergoes significant intercontinental transport which in the Northern Hemisphere is preferentially north resulting in deposition on northern snow mass. Unlike CO_2 which has long residency in the atmosphere, black carbon ultimately does deposit and hence is called a short-term climate forcer via its northern polar impacts. The impact on climate and secondary impacts on atmospheric chemistry link black carbon to potential worsening air health as climate evolves in the future through its contribution to the formation of other pollutants such as O_3.

Chronic Effects and Cancer In 2013, the WHO's International Agency for Research on Cancer (IARC) examined the published science and concluded that air pollution causes lung cancer (Straif et al., 2013). Moreover, based on published data, the committee concluded that the component of air pollution most likely responsible was PM due to the complexity of carcinogenic components (polycyclic aromatic hydrocarbons [PAHs]) that comprise PM. The cumulative epidemiology literature is largely consistent with this assessment (Hamra et al., 2014). Linked to the PM is its composition of complex organic compounds (e.g., PAHs), which in part are thought to be linked to diesel exhaust, which IARC designated as a primary human carcinogen in 2012 largely based on studies involving occupational exposures to diesels in mines (Silverman et al., 2012). Hence, the carcinogenicity issue appears to be generally accepted by the scientific community. It should be noted, however, that post 2007 heavy duty diesel engines have been re-engineered and most possess filters greatly (more than 99%) reducing PM and its empirical carcinogenicity (HEI, 2015a).

Cigarette smoking (also replete with PAHs) remains a confirmed cause of lung cancer and clearly associated with other systemic cancers. The IARC assessments and U.S. cohort studies, such as that using the American Cancer Society (ACS) cohort (Pope et al., 2011), show a significant linkage between ambient PM and lung cancer in the United States even at the generally lower PM levels compared other countries. Yet, at the same time, it has been difficult to separate PM cancer from those cancers that appear linked to the many hazardous air pollutants (HAPs) that occur in urban air and are also thought to be carcinogenic. Many suspect HAPs, but few (about 10%) of the more than 2800 compounds that have been identified in the air have been assayed for carcinogenic potency. Fig. 31-15 gives estimates of the relative contributions of various chemicals to the lung cancer risk for outdoor and indoor air (Loh

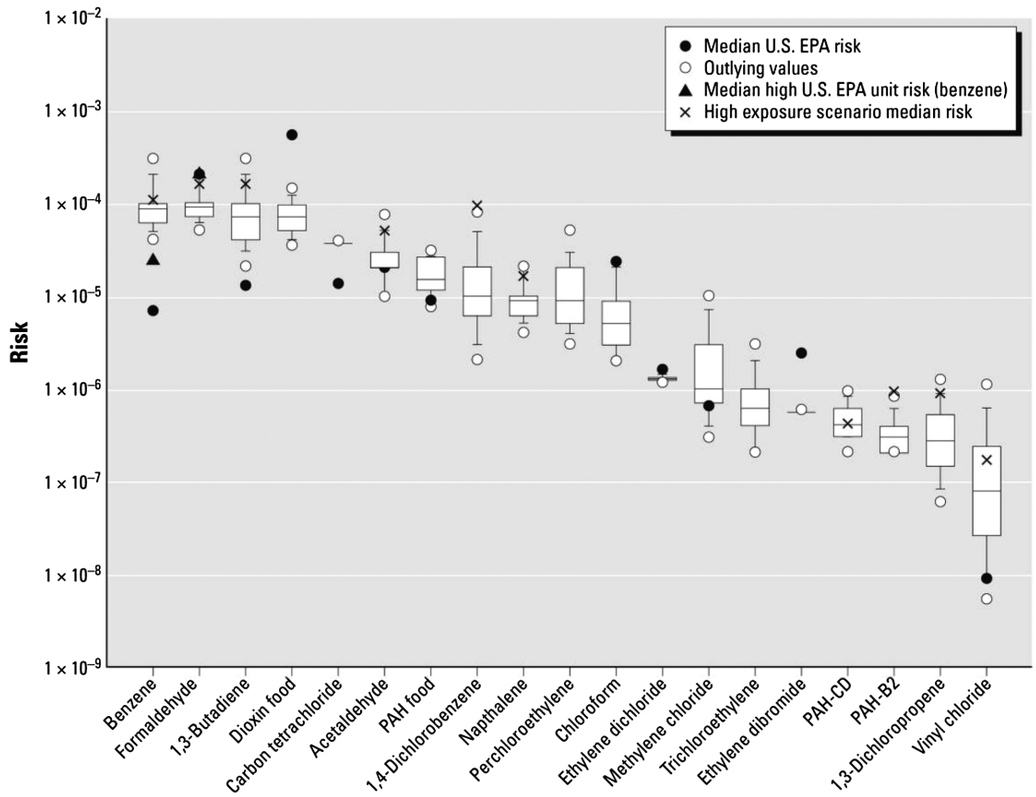

Figure 31-15. *Relative contribution of individual airborne hazardous pollutants to lung cancer rates using California Office of Environmental Health and Hazard Assessment (OEHHA) and U.S. EPA unit risks (Loh et al., 2007).* The symbols reflect unit risks for the inhalation route of exposure (except as noted for food) at home and outdoors. Bars represent 5% and 95% and boxes represent 25%, 50%, and 75%. PAH = polyaromatic hydrocarbons grouped into B2 (evidence of carcinogenicity in animal studies) and CD (less experimental evidence).

et al., 2007). Volatile and related halogenated organic and nitrogen-containing compounds account for most of the compounds that have been studied with animal and genotoxicity bioassays. Most of these compounds are derived from combustion sources ranging from tobacco to power plants to incinerators to motor vehicles. Other potential carcinogens arise from mobile sources as organic emission products of incomplete combustion as well as their even more complex atmospheric transformation products. Fugitive or accidental chemical releases also figure into the many chemicals in ambient and indoor air. The National Scale Air Toxics Assessment (NATA) is an assessment of the cancer and noncancer risks associated with ambient HAPs (U.S. EPA, 2018). The profile of outdoor carcinogens contrasts with that of indoor air, where the sources are thought to derive largely from environmental tobacco smoke and radon, with some contribution from off-gassed organics (e.g., adhesives, carpet polymers, and cleaning chemicals). Thus, human exposure to airborne toxicants is highly complex compositionally as well as in its temporal and spatial heterogeneity.

Despite all the evidence linking air pollution with lung cancer, the risk of any individual is a complex function of the carcinogenic nature of the substance, the amount, and nature of material deposited in the lungs, which is itself a function of the concentration in the ambient air, the physical and chemical properties of the inhalant that may determine deposition efficiency, innate repair mechanisms, and the cumulative volume of air inhaled. A significant body of data suggests that the majority of lung cancer risk from ambient air pollution lies within the PM fraction. Among the many potent chemicals are the polycyclic organic chemicals, along with a group of less volatile organics sometimes referred to as "semi-volatiles" (including nitroaromatics). These persistent organics associate with the PM matrix and thus could have a prolonged residence time at deposition sites within the respiratory tract. Genetic bioassays have revealed the potent mutagenicity, and presumably carcinogenicity, of various chemical fractions of ambient aerosols (Lewtas, 2007). Some of these compounds require metabolic transformation to activate their potency while others may be detoxified by their metabolism. Not to be forgotten are the VOCs noted earlier that are likely carcinogenic (e.g., benzene) and which are inhaled but have target tissues away from the lung—in the case of benzene, bone marrow leukemia.

Not to be undervalued is that the innate susceptibility of the individual (including genotype-driven characteristics and environmental factors such as diet) is also likely to be important. The cells lining the respiratory tract turn over relatively quickly as they interface directly with the ambient environment with every breath. As such, their DNA would be vulnerable to carcinogenic or oxidant-induced replication errors from inhaled substances that, when fixed as mutations, could give rise to tumors. Co-pollutants, such as irritant gases, that initiate inflammation may promote this carcinogenic activity by damaging cells and enhancing their turnover. For example, there is experimental evidence that benzo(*a*)pyrene inhaled by rats whose respiratory tracts have been chronically exposed to SO_2 are prone to bronchogenic carcinomas. Likewise, epidermoid carcinomas were produced in mice that inhaled ozonized gasoline vapors, containing reactive organic products, but this occurred only if the mice had previously been infected with influenza virus and presumably had inflamed lungs. Many believe that the so-called rural–urban gradient of lung cancer, apparent even when corrected for cigarette smoking, is a product of such complex chemical–biological interactions. Thus, while the initiation of environmental lung cancer remains poorly understood, there is general sentiment for the opinion expressed early-on by Kotin and Falk (1963): "Chemical, physical and biological data unite to form a constellation that strongly implicates the atmosphere as one dominant factor in the pathogenesis of lung cancer." At the time of this statement, however, even the role of tobacco smoke in cancer was not widely recognized.

To understand the role of inhaled particles in non-cigarette-smoke-related lung cancer, chronic exposure studies have been conducted with a number of particles ranging from the relatively inert particles of titanium dioxide and carbon to the more complex particles of diesel exhaust and coal fly ash. Of these substances, diesel exhaust has been the most extensively studied (reviewed by Ghio et al. [2012] and HEI [2015b]). The primary concern with diesel has been the long-held suspicion that it can induce lung cancer (as noted now as an IARC—designated human carcinogen). While the assembled epidemiology data on diesel exhaust formed the basis of the IARC designation of diesel exhaust (including the PM and gases) as a primary carcinogen, the empirical studies of carcinogenicity alone has long been suggested by several chronic exposure studies in animals and by in vitro data indicating mutagenicity in *Salmonella* bacteria and enhanced sister chromatid exchange rates in Chinese hamster ovary cells. (These latter genotoxic effects have been linked to the nitroarenes associated with the diesel PM.) Rodent studies, unfortunately, have not fully provided great insights as to the mechanisms involved other than the relatively generic—mutation/inflammation—pathways, and it has only been at very high exposures in which mucociliary clearance has been sufficiently overwhelmed allowing in a progressive buildup of particles in the lungs leading to what has been termed "overload" (see below). By 12 months into exposure, in the rat, clearance has ceased and there is concomitant inflammation, oxidant generation, epithelial hyperplasia, and fibrosis. Particle agglomerates within the alveolar lumen become the focus of inflammation, injury, and the eventual development of adenosarcomas and squamous cell carcinomas. At lower concentrations, where the particle buildup (i.e., overload) does not occur, tumors do not develop.

"Overload" is a common finding at the highest exposure concentrations of chronic particle inhalation bioassays. While this phenomenon is not likely in humans exposed to ambient PM, it is a hypothesis worthy of consideration in a discussion of particle health effects, as it relates to the interpretation of toxicological data relevant to product use and industrial exposures. Several poorly soluble particles (PSPs), such as titanium dioxide and toner carbon, have induced lung tumors in chronic rat bioassays under conditions of overload; tumors have not developed under similar conditions in mice and hamsters. Thus, rats seem to react more to this circumstance. Particles in the ultrafine mode seem particularly potent. In the rat, pathogenesis is qualitatively and temporally the same for all of the particle types tested. In contrast, the degree of active inflammation in the mouse and hamster under similar overload conditions appears less intense, and thus is an important distinction among the species that relates to their relative sensitivities. Such exposures do not typically demonstrate classic genotoxicity, although bulky adducts and other modifications to DNA have been described after in vivo exposure to carbon black and diesel exhaust (reviewed by Schins and Knaapen [2007]). In addition, mutation of the *hprt* (hypoxanthine guanine phosphoribosyltransferase) gene was found in rat epithelial cells cultured with bronchoalveolar lavage from chronic carbon black and titanium dioxide treated rats (Driscoll et al., 1997).

Even though these few studies have demonstrated inert particle-induced modifications to DNA, generalizing this finding to overload cancers, not surprisingly, remains controversial. Typically, the pathways leading to lung cancer by relatively inert and poorly soluble particles (e.g., carbon black and diesel exhaust particles) are thought to be secondary and involve pathways such as oxidative

stress rather than a primary carcinogenesis mechanism such as DNA mutations (Greim et al., 2001). The closest analogy in humans would be coal miners who do not appear to have an enhanced risk of lung cancer except when smoking is not involved.

The issue, then, is whether rat bioassay cancer data under conditions of overload are relevant to risk assessment. A review by an expert panel (Olin, 2000) concluded that rats, while apparently unique in this response, may represent a sensitive subgroup, and that tumorigenesis data from the rat bioassay under conditions of overload cannot be summarily dismissed as not relevant to the consideration of cancer risk in humans. However, the data should be interpreted and weighed in the context of lower concentrations and the tumor incidence and pathology found therein.

Photochemical Air Pollution

Photochemical air pollution (notably O_3) remains the most elusive of the criteria pollutants in ambient air to bring under regulatory control. It is estimated that more than 130 million Americans reside in areas not in compliance with the health-based standard and hence are at some risk of adverse health impacts. Ozone arises secondarily from a series of complex reactions in the troposphere activated by the ultraviolet (UV) spectrum of sunlight. In addition to O_3, it comprises a mixture of nitric oxides (NO_x), aldehydes, peroxyacetyl nitrates (PAN), and a myriad of aromatics and alkenes along with analog reactive radicals and intermediates. If SO_2 is present, sulfate particles may also be formed and, collectively, they yield "summer haze." Likewise, the complex chemistry can generate organic PM, nitric acid vapor, and various condensates. Attempts to mitigate photochemical smog (especially O_3) by controlling hydrocarbon and/or NO_x emissions have proven difficult due to the complex stoichiometry of atmospheric photochemistry. Some progress has been made in controlling peak values in the United States (regulated by the pre-1997 1-hour NAAQS), but the longer time-framed 8-hour NAAQS has seen generally smaller progress. Because of particularly strong regulatory efforts in Southern California, however, the average number of high ozone days per year dropped by 33% between 2000 and 2010 in the Los Angeles–Long Beach–Riverside metropolitan area, the most polluted part of the United States, in terms of ambient ozone levels, and high ozone days continue to decrease (American Lung Association, 2017). In 2016, Los Angeles experienced fewer high ozone days than previously recorded.

From the point of view of the toxicology of photochemical air pollutant gases, O_3 is by far the toxicant of greatest concern. It is highly reactive and more toxic than NO_x, and because its generation is fueled through cyclic hydrocarbon radicals, it reaches greater concentrations than the hydrocarbon radical intermediates. The gaseous hydrocarbons, so integral to the chemistry, are no longer listed collectively as a criteria pollutant in the United States because they do not have a strong health-based driver. In general, the concentrations of the hydrocarbon precursors in ambient air do not reach levels high enough to produce acute toxicity, although some individual compounds fall under the HAPs rule. Rather, the importance of these hydrocarbons stems from their role in the chain of photochemical reactions.

Although O_3 is of toxicological importance in the troposphere, in the stratosphere it plays a critical protective role. About 10 to 50 km above the Earth's surface, UV light directly splits molecular O_2 into atomic $O^{\bullet}$, which then combines with O_2 to form O_3. The O_3 also dissociates back but much more slowly. The result is an accumulation of O_3 to several ppm within a relatively thin strip of the stratosphere forming an effective "permanent" barrier by absorbing the short-wavelength UV in the chemical process. This barrier had in recent years been threatened by various anthropogenic emissions (Cl_2 gas and certain chlorofluorocarbons) that enhance O_3 degradation (creation of an "O_3-hole"), but recent restrictions in the use of these degrading chemicals seem to have been effective in reversing this process, although recently concern is mounting that the hole may be growing again due to the release of other halogenated gases. The benefits of this stratospheric O_3 are the reduction of excess UV light infiltration to the Earth's surface and reduced skin cancer risk.

The impact of O_3 in the troposphere, where its accumulation serves no known purpose, poses a threat to the respiratory tract when inhaled. Near the Earth's surface, NO_2 arising from combustion processes efficiently absorbs the longer wavelength UV light spectrum, from which a free O atom is cleaved, initiating the following simplified series of reactions:

$$NO_2 + h\nu(\text{UV light}) \rightarrow O^{\bullet} + NO^{\bullet}. \quad (31\text{-}1)$$

$$O^{\bullet} + O_2 \rightarrow O_3. \quad (31\text{-}2)$$

$$O_3 + NO^{\bullet} \rightarrow NO_2. \quad (31\text{-}3)$$

This process is inherently cyclic, with NO_2 regenerated by the reaction of the $NO^{\bullet}$ and O_3. In the absence of unsaturated hydrocarbons (olefins and substituted aromatics) arising from fuel vaporization or combustion, as well as biogenic terpenes, this series of reactions would approach a steady state with little buildup of O_3. The free electrons of the double bonds of unsaturated hydrocarbons are attacked by free atomic $O^{\bullet}$, resulting in oxidized compounds and radicals that react further with $NO^{\bullet}$ to produce more NO_2. Thus, the balance of the reactions sequence shown in Eqs. (31-1) to (31-3) is tipped to the right, leading to buildup of O_3. This reaction is particularly favored when the Sun's intensity is greatest at midday, utilizing the NO_2 provided by morning rush-hour traffic. Carbonyl compounds (especially short-chained aldehydes) are also by-products of these reactions. Formaldehyde and acrolein account for about 50% and 5%, respectively, of the total aldehyde content in urban atmospheres. Peroxyacetyl nitrate (CH_3COONO_2), often referred to as PAN, and its homologs also arise in urban air, most likely from the reaction of the peroxyacyl radicals with NO_2. In the evening when the Sun's intensity wanes, the second rush-hour peak of NO_2 shifts the balance back by reacting with O_3 slowly bringing the daytime peak concentration down. In assessing the excess adverse health effects of O_3, it is important to determine the background level of ambient O_3. Interestingly, background levels of ozone in North America are known to peak as high as 0.14 ppm (1 hour), particularly in high elevation regions such as Wyoming, although the contribution of these transient 1 hour levels of ozone to general public health is unclear. This high altitude peak concentration is thought to be due to a combination of high VOC levels, NO_x, and the additional UV light reflected off snow cover. However, other factors such as season, thickness of boundary layers, vertical intrusions from the stratosphere, and long range transport also play roles in determining background levels of O_3 in North America. The recent growth in natural gas fracking operations along the eastern range of the United States has resulted in fugitive losses of methane which may also be contributing to O_3 formation. This issue is highly controversial and shows the tenuous temporality of any intervention to reduce air pollutants formed secondarily due to complex chemistry.

Short-Term Exposures to Smog

During the 1950s to 1960s, early air pollution toxicologists were challenged by the complexity of photochemical air pollution to ascertain its potential both to adversely affect human health and to

determine what about these atmospheres was responsible for the effects. The focus was immediately placed on O_3 because its toxicity was found to be high even at low ppm concentrations. Concerns that the complex atmosphere might be even more hazardous led to a number of studies with actual (outdoor-derived) or synthetic (photolyzed laboratory–prepared) smog to assess the potency of the ambient-like pollution mixtures. When human subjects were exposed to real-world photochemical air pollution (Los Angeles ambient air pumped into a laboratory exposure chamber), they experienced changes in lung function similar to those described in controlled clinical studies of O_3 alone (i.e., reduction in spirometric lung volumes), thus supporting the view that O_3 was the pollutant of primary concern. Acute animal studies using synthetic atmospheres (usually irradiated auto exhaust) provided supportive evidence indicating deep lung damage, primarily within the small airway and proximal alveolar epithelium.

As a result, O_3 was the focus in many of early air pollution studies despite a modicum of evidence that co-pollutants might also be involved in eliciting the effects observed with smog. For example, when guinea pigs were exposed to irradiated auto exhaust, airway resistance increased quickly, which contrasts with the pattern of O_3-related dysfunction that expresses as an increase in breathing rate. Perhaps a more soluble irritant(s) was involved, such as reactive aldehydes, but these pollutants were not monitored. With the potency of O_3 so apparent, attention was drawn to its effects and less to the array of seemingly less dramatic effects of a complex atmosphere. Even today, the focus on smog is almost exclusively centered on O_3 so it is not too surprising that the regulatory perspective is also tied to this single pollutant.

Chronic Exposures to Smog

Epidemiological studies in human populations as well as empirical studies in animals have attempted to link degenerative lung diseases with chronic exposure to photochemical air pollution. Cross-sectional and prospective field studies have suggested an accelerated loss of lung function in adults living in areas of high pollution; however, as with many such studies, there were problems with confounding factors (meteorology, poor exposure assessment, and confounding variables).

Studies conducted in children living in modern-day Mexico City, which has oxidant and PM levels far in excess of any city in the United States, have found abnormalities in the nasal epithelium using it as exposure surrogates for deep lung effects as would be assayed by invasive biopsy and lavage methodologies. Dramatic effects were reported in exposed children, consisting of severe epithelial damage and metaplasia as well as permanent remodeling of the nasal epithelium. When children migrated into Mexico City from cleaner, nonurban regions, even more severe damage was observed, suggesting that the tissue remodeling in the permanent residents imparted some degree of incomplete adaptation. Because the children were of middle-class origin, these observations were less likely confounded by socio-economic variables (Calderon-Garcidueñas et al., 1992). Changes in lung hyperinflation as estimated by x-ray tomography and impaired lung function along with markers of oxidative stress have been reported among similarly exposed children living in Mexico City (Calderon-Garcidueñas et al., 2003; Hernández-Escobar et al., 2009) raising further concerns of long-term effects.

Many studies have focused on children living in variably polluted areas of the Los Angeles basin showing the impact of air pollution—O_3 and PM—on lung growth, lung function, and other growth-related variables from childhood through high school age. Recently, a study examined the improvement of many of these variables as air quality has improved in various communities over a 13-year period. Improved lung function could be attributed to decreases in PM, NO_2, but less so with O_3 which itself changed less than the other primary pollutants (Gauderman et al., 2015).

A now-classic synthetic smog animal study was undertaken at the Cincinnati EPA laboratory in the mid-1960s in an attempt to address the potential for long-term lung disease. Beagle dogs were exposed on a daily basis (16 hours) for nearly 6 years, followed by a clean-air recovery period of about 3 years (Lewis et al., 1974). A series of physiologic measurements were made on the dogs after the exposure, and after their 3-year recovery. They were then moved to the University of California at Davis. The lungs of the dogs then underwent extensive morphologic examination to correlate with the physiology measurements. The dogs had been exposed to non-irradiated auto exhaust, irradiated auto exhaust, SO_2 plus sulfuric acid, the two types of exhaust plus the sulfur mixture, and a high and a low level of NO_x. The atmospheres were quite complex with only the irradiated exhaust mixtures containing O_3 and NO_2 and all contained CO. In short, all the mixture exposure groups had functional abnormalities, most of which persisted or worsened over the 3-year recovery period in clean air with enlargement of airspaces and loss of interalveolar septa consistent with emphysema and chronic obstructive pulmonary disease (COPD) (Hyde et al., 1978). The degenerative and progressive nature of the smog-induced lesions was reminiscent of lung disease with lifelong tobacco smoking.

Long-term "sentinel animal" studies in highly polluted cities have shown similar abnormalities, although some have been confounded by background infection due to the nature of the study. One such study, conducted in rats exposed for 6 months to the air of São Paulo, Brazil, found considerable airway damage, lung function alterations, and altered mucus rheology (Saldiva et al., 1992). This collage of effects is not unlike a composite of injury one might suspect from a mixed atmosphere of oxidants and acid PM in controlled laboratory animal studies. Strangely enough, however, a 7-week study in rats exposed to the polluted Mexico City air, which had induced significant lesions in children, did not reveal nasal or lung histopathology in F-344 rats (Moss et al., 2001). Thus, the evolution of air pollution–induced lung disease has potentially many variables, but overall there is coherence that long-term exposure of children and experimental animals to urban polluted atmospheres has long-term negative consequences on lung health.

Ozone

General Toxicology Ozone is the primary oxidant of concern in photochemical smog because of its inherent bioreactivity and its concentration relative to other reactive species. Approximately 140 million Americans lived in areas not in compliance with the 8-hour NAAQS in 2016. Progress has been made in reducing ambient O_3 levels and Los Angeles, for example, has not exceeded the Stage 1 smog alert (1-hour peak of 0.20 ppm or more) since 1998; it has dropped the number of exceedances of the 0.075 ppm (2006) NAAQS in half from 1990 to 2011. Unlike SO_2 and PM reductions that have largely been done at their source, mitigation strategies for O_3 have been somewhat less successful despite significant reductions in automobile emissions. Reductions in O_3 have been partially offset by population growth, which brings with it additional vehicles and vehicle miles driven. With suburban sprawl and the downwind transport of air masses from populated areas to more rural environments, the geographic distribution of those exposed has also expanded, as has the temporal profile of individual exposure. In other words, ambient O_3 exposures are no longer stereotyped as

brief 1- to 2-hour peaks as in the 1960s and 1970s. Instead, O_3 forms over longer drive periods and transport of pollutants spreads the period of exposure to 6 hours or more at or near the NAAQS level. This important change in the exposure profile to O_3 has given rise to concerns that cumulative impacts occur over an exposure of several hours rather than what one might experience with shorter pulse-like exposures. It is feared that many more people might be at risk than previously thought. With the 1997 revision of the U.S. O_3 NAAQS to include an 8-hour daily average of 0.08 ppm, more cities and suburban areas found themselves in violation of the standard. If indeed the damage to the lung is cumulative over an 8-hour time period, then people in areas of compliance but with exposure levels near the standard may be affected. The most recent revision of the O_3 NAAQS reduced the level to 0.07 ppm (2015). The American Lung Association estimates that nearly 50% of U.S. inhabitants live in counties that are not in O_3 compliance (American Lung Association, 2017).

Ozone induces a variety of effects in humans and experimental animals at concentrations that occur in urban areas (reviewed by Lippmann [1989] and U.S. EPA [2013]). These effects include morphologic, functional, immunologic, and biochemical alterations mostly in the lungs. Because of its low water solubility, a substantial portion of inhaled O_3 penetrates deep into the lung, but its reactivity is such that about 17% and 40% are scrubbed by the nasopharynx of resting rats and humans, respectively (Gerrity et al., 1988; Hatch et al., 1994). The reason for the higher degree of scrubbing in humans is unclear, but the finding is reproducible. Moreover, the mouth appears to scrub as well as the nose. Nevertheless, regardless of species, the region of the lung that is predicted to have the greatest O_3 deposition (dose per surface area) is the centriacinar region, from the terminal bronchioles to the alveolar ducts, also referred to as the proximal alveolar ductal region (Overton and Miller, 1988). Because O_3 penetration increases with increased tidal volume and flow rate, exercise increases the dose to the target area. Using $^{18}O_3$ (a nonradioactive isotope of oxygen), Hatch et al. (1994) have shown that the dose to the distal lung and the degree of damage to the lung as determined by leakage of plasma protein into the alveolar space (as collected by bronchoalveolar lavage) in exercising human subjects are similar to the magnitude of inflammation and protein leak in rats exercising or at rest but exposed to higher ventilation-adjusted concentrations. Thus, it is important to consider the role of exercise-associated dosimetry in a study of O_3 or any inhalant before making cross-study comparisons, especially if that comparison is across species.

Animal studies indicate that the acute morphologic responses to O_3 involves epithelial lining cells along the entire respiratory tract. The pattern of injury parallels the dosimetry profile, with the majority of damage occurring in the distal lung. Along the conducting airways, ciliated cells appear to be most sensitive to O_3, while Clara cells and mucus-secreting cells are the least sensitive. Studies in the rat nose indicate that O_3 also is an effective mucus secretagogue. In the alveolar region, type 1 epithelial cells are very sensitive to O_3 relative to type 2 cells, which have an active metabolic machinery and can also serve as the stem cells for the replacement of damaged type 1 cells. At lower concentrations (less than 0.8 ppm in the rat), a single exposure is followed by recovery with no residual pathology after a few days. In humans, a single exposure to high ambient levels of O_3 results in airways that appear "sunburned" when a bronchoscope is used to peer into the human bronchus. What is uncertain is the impact of repeated "sun-burning" of the airways and lung.

Studies have shown particular sensitivity to O_3-induced inflammation in neonatal rats; effects decrease with age into adulthood. However, enhanced sensitivity to O_3 again appears in older rats as evidenced by interstitial edema that is not seen in younger adult animals. Older rats have lower ascorbate in the lung and this diminishment of antioxidant capacity may be in part responsible. Ascorbate in humans has been found to reduce the lung function effects in controlled exposures and other antioxidant compounds seem to have similar albeit varied impacts (Tashakkor et al., 2011). Elderly humans, however, seem less responsive to the lung function impacts of high ambient O_3. The reasons for this are unclear, but caution is warranted in linking lung function and inflammation in the O_3 response.

The mechanisms by which O_3 causes injury have been studied using cellular as well as cell-free systems. As a powerful oxidant, O_3 seeks to extract electrons from other molecules. The surface fluid lining the respiratory tract and the cell membranes that underlie the lining fluid contain a significant quantity of polyunsaturated fatty acids (PUFA), either free or as part of the lipoprotein structures of the cell. The double bonds within these fatty acids have a labile, unpaired electron that is easily attacked by O_3 to form ozonides that progress through a less stable zwitterion or trioxolane (depending on the presence of water); these ultimately recombine or decompose to lipohydroperoxides, aldehydes, and hydrogen peroxide. These pathways are thought to initiate propagation of lipid radicals and autooxidation of cell membranes and macromolecules (Fig. 31-16).

Evidence of free radical–related damage in vivo includes detection of exhaled breath pentane and ethane and tissue measurements of diene conjugates. Damage to the air–blood interface disrupts its barrier function and promotes inflammation. Inflammatory cytokines (e.g., interleukins 6, 8, and others, and TNF) are released from epithelial cells and macrophages that mediate early responses and initiate repair. This inflammatory process is generally transient, but it may also interact with neural irritant responses to affect lung function acutely. This latter response may have implications for those with preexistent inflammation or disease.

Pulmonary Function Effects Exposure to O_3 produces a variety of pulmonary function changes; unlike with the inflammation effect, humans appear to be more sensitive than most animal models. Although the human studies almost always involve exercise, their deficit in lung function occurs more rapidly and is more dramatic than animals that have been tested similarly. It is noteworthy that in controlled human studies involving O_3, considerable interindividual differences in response have been observed that are linked to individual physical and biological features as well as

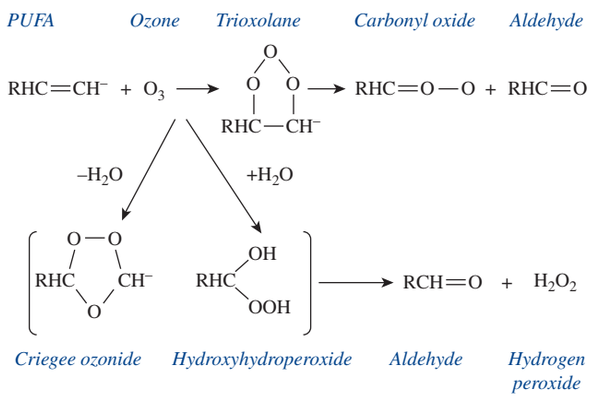

Figure 31-16. *Major reactions pathways of O_3 with lipids in lung lining fluid and cell membranes.* (Adapted with permission from U.S. EPA [2013].)

possibly genetic factors. Animal studies show similar host factors of susceptibility.

It is not entirely clear what mechanisms underlie the altered lung function (in terms of changes in FEV_1) produced by O_3. Chest pain/discomfort on deep breathing is thought to contribute to O_3-induced decreases in an effort-dependent lung function maneuver such as FEV_1. These are thought to be vagally mediated and involve C-fiber stimulation; the responses can be abrogated by analgesics, such as ibuprofen and opiates, which also reduce pain and inflammation (see below). Thus, pain reflexes involving C-fiber networks are thought to be important in the reduction in forced expiratory volumes. Animal studies also show a prominent role for vagal reflexes in altered airway responsiveness and bronchoconstriction. There is also evidence to implicate vagal reflexes in cardiac as well as corporal thermal regulation, at least in rodents, as part of a nonspecific defense mechanism decreasing ventilation.

Airway responsiveness to specific (e.g., allergen) and nonspecific (e.g., cold air and inhaled methacholine) bronchoconstriction is another commonly used test of the pulmonary response to inhaled pollutants such as O_3. These types of tests are very important because airway hyperresponsiveness is a central feature of asthma and asthmatics are a sizeable subpopulation (7% to 9% of the total population in the United States and 1% to 18% worldwide) that may be particularly sensitive to the adverse respiratory effects of inhaled pollutants. A number of animal models have demonstrated that O_3 induces airway hyperresponsiveness and that innate factors such as genetics, diet, and obesity can modify this effect. For the most part, many of these studies have utilized O_3 exposure concentrations that are far above ambient levels. Importantly, controlled human exposure studies have not only verified the findings of the high dose animal studies, but also demonstrated adverse effects at concentrations relevant to ambient O_3 levels. Airway hyperresponsiveness to nonspecific agonists in humans has been reported after acute exposure to as little as 0.08 ppm O_3. It is widely thought that hyperreactive airways may be a marker of predisposition to other pollutants or aeroallergens.

Inflammation of the Lung and Host Defense The mechanism by which O_3 produces decrements in pulmonary function appears to be largely neurologic, but the cross-links with airway inflammation are unclear. For example, O_3-induced lung dysfunction does not appear to be enhanced in asthmatics whose lungs are generally in a state of inflammation, yet asthmatics are more sensitive to the bronchoconstrictive effects of both SO_2 and sulfuric acid aerosols. It may be that inflammation sensitizes nerve endings to external irritants. Age and obesity in animal models suggests these factors may also play a role in the pulmonary response to O_3. These studies have demonstrated that O_3-induced lung injury and inflammation is greater in neonatal compared to adult rabbits, rats, and mice (Vancza et al., 2009). Obesity predisposes mice to O_3-induced inflammation and airway hyperresponsiveness as well (Williams et al., 2015). Because obesity is associated with ongoing systemic inflammation, it suggests that a preexisting physiologic or disease state enhances the adverse effects of O_3.

Both human and animal studies have demonstrated that sensitivity to O_3 appears to have a genetic component as well. Studies in inbred stains of mice have shown that O_3-induced pulmonary neutrophilia, airway hyperresponsiveness, and permeability are significantly affected by SNPs in a single gene linked to the Toll-like receptor 4 (Tlr4) locus that has been associated with endotoxin sensitivity (Kleeberger et al., 2000). Further research has determined that the participation of an innate immunity factor, such as Tlr4, in the multifaceted response to O_3 involves the release of hyaluronan fragments that appear to directly activate the Tlr4 cascade in mice (Li et al., 2011). The role of genetic polymorphisms in the pulmonary response to O_3 is complicated, however, and many other pathways including TNF, IL-1, Nrf-2, and NF-κB can modulate the response to O_3 in animal models (Bauer and Kleeberger, 2010).

The growth of genomic and proteomic technologies has made it possible to begin studies in humans to define genetic linkages to O_3 sensitivity. These studies have typically focused on genes involved in oxidative stress pathways. For example, again using Mexico City as a backdrop, it was found that a polymorphism in glutathione-*S*-transferase Mu 1 (GSTM1) appears to convey O_3 sensitivity (Romieu et al., 2004). Similarly, functional polymorphisms in the catalase and myeloperoxidase genes have been associated with enhanced response to ambient ozone. More detailed, controlled exposure O_3 studies in humans have confirmed that genetic polymorphisms in these and other genes, including NAD quinone oxidoreductase (NQO), GSTP1, heme oxygenase-1, and tumor necrosis factor (TNF), which are associated with responsiveness to O_3 and that gene–gene interactions are involved.

The strong epidemiologic evidence that O_3 can exacerbate asthma (e.g., increased hospital admissions) is strong, but causal ties to exacerbated immune responses have depended on empirical exposure studies. The potential for O_3 to influence allergic sensitization and/or challenge-responses has received a significant amount of investigation in both human and animal studies. Controlled human exposure studies have shown that asthmatics respond in a manner not overly dissimilar from normal, but because asthmatics have less functional reserve, lung function deficits are more evident (Kehrl et al., 1999). There is also evidence of heightened airway responsiveness to nonspecific airway challenges—pharmacologic agents, cold air, exercise, etc. Exaggerated responsiveness to allergens in allergic subjects has also been reported but seems less consistent or antigen-dependent, with variable evidence of lung function impacts yet more demonstrable enhancement of inflammation with changes in immune cell phenotypes and oxidative stress (Alexis and Carlsten, 2014). Likewise, eosinophils and IL-4, central components of allergic asthma, have also been reported to be increased in some but not all human chamber studies of O_3 exposure (U.S. EPA, 2013). Diary studies of asthmatic nurses, which involve a broader range of susceptibility, however, report worsened allergy symptoms, as well as durations thereof, at concentrations of O_3 near the NAAQS (Schwartz, 1992); similar results have reported in children in Southern California (Malig et al., 2016).

Enhanced response to allergen challenge has also been noted in a number of animal species exposed to O_3. Biochemical, cellular, and pulmonary function parameters of allergic response have all been observed to increase in sensitized animals exposed to O_3 prior to antigen challenge. Ozone's effect on allergic asthma also appears to occur at the sensitization stage in which repeated exposure to O_3 before or during the sensitization process exacerbates a range of allergic endpoints. Thus, in general, animal studies have shown the ability of O_3 to enhance both attributes of the allergic process, while the evidence in humans lies only in the exacerbation of response and this attribute itself.

Regarding other immune responses, early research showed that exposure to O_3 before a challenge with aerosols of infectious agents produced a higher incidence of infection than is seen in control animals (Coffin and Blommer, 1967). Studies show that this type of effect can be a direct result of altered phagocytosis by macrophages in O_3-exposed mice previously infected with an aerosol of *Streptococcus* (group C) bacteria (Gilmour et al., 1993). The host resistance model has shown responsiveness to an exposure as low as 0.08 ppm for 3 hours—perhaps the most sensitive

model that exists for O_3. The susceptibility of mice and hamsters to *Klebsiella pneumoniae* aerosol is also increased by prior exposure to O_3. In the rat, altered microbe-killing may relate to membrane or receptor damage in macrophages, thus impairing the production of bactericidal agents such as superoxide anions. Overall, the rat appears less susceptible than mice because it has a more vigorous polymorphonuclear leukocyte (PMN) response to bacteria than do mice, which seems to compensate for macrophage impairments. This is yet another example of where susceptibility lies more in the inability to compensate than in the initial responsiveness to a given challenge. It is not clear whether O_3's impairment of bacterial infections in the lung also extends to viral infections. While ambient O_3 has been associated with increased hospital admissions for viral and bacterial infections, animal studies show mixed results for O_3's effect on viral infections, although some of the contradictory findings may be a result of experimental design differences (e.g., O_3 exposure occurring before or after viral infection).

Chronic Effects Morphometric studies of the centriacinar region of rat lungs exposed for 12 hours per day for 6 weeks to 0.12 or 0.25 ppm O_3 show hyperplasia and hypertrophy of type 1 alveolar cells (smaller and thicker cells) coupled with damage and alterations in ciliated and Clara cell populations in upstream small airways (Barry et al., 1988). A collective cross-protocol analysis of type 1 cell hypertrophy was conducted, and type 1 cell thickness appeared to be linearly related to the O_3 $C \times T$ (Chang et al., 1991, 1992). This finding suggested that over a season, the impact of O_3 in the distal lung may be cumulative and perhaps more importantly may be without threshold. The biological significance of this change is unclear—it may be part of a compensatory response to "thicken" that part of the alveolar-duct junction that receives the greatest dose and is most affected. This response may thus protect because the thickened cells are smaller, offering less exposure-surface for the incoming O_3 and therefore limiting membrane damage. When returned to clean air, most of this epithelial pathology regressed, but there was nonetheless evidence of residual interstitial remodeling beneath the epithelium in the alveolar-duct region.

A long series of studies at the University of California, Davis has examined the structural and functional changes produced in nonhuman primates exposed chronically to O_3. Because of the greater similarity of monkey respiratory tract to that of humans, the burden of extrapolation to humans is lessened and has proven important in establishing causality for analogous epidemiology studies. Daily 8-hour exposures to 0.2 ppm O_3 for 90 days produced cellular changes throughout the respiratory tract, including the nose. In the second phase of these studies, infant rhesus monkeys were cyclically exposed to 0.5 ppm O_3 for 8 h/day for 5 days followed by several days of exposure to air. While the study design didn't permit a direct comparison of the responsiveness of infant versus adult monkeys, the infant monkeys showed evidence of structural changes that parallel epidemiology studies in children. The infant monkeys also showed a significant interaction between sensitization to house dust mite antigen and ozone. While antigen or O_3 alone produced small changes in baseline airway resistance and airway responsiveness, antigen plus O_3 produced more than additive effects on both parameters.

Studies involving episodic exposures of rats and monkeys using a pattern of alternating months of O_3 (0.25 ppm) for 18 months indicated a range of effects, notably thickening of interstitial fibrous matrix (Tyler et al., 1988), suggesting loss of lung compliance. These interstitial changes were quantitatively similar for the continuous and intermittent exposure profile despite the twofold difference in the cumulative exposure dose (i.e., $C \times T$). This would imply that a pattern of exposure resembling seasonal O_3 patterns, with real-world relevance, might result in more serious lesions than predicted by dose alone—perhaps even more than would have occurred had the exposure been continuous. Hence, the concept of "more dose . . . more effect" may not hold in chronic episodic scenarios for O_3, as it appears with uninterrupted exposures. The number of episodes experienced may well be more significant to long-term outcomes than total dose—a phenomenon not unlike that of repeated sun-burning and deterioration of the skin.

Studies of lung function in rodents exposed chronically to O_3 have yielded mixed results at relevant exposure concentrations. Generally, the observed dysfunction is reflective of stiffened or fibrotic lungs, particularly at higher concentrations. There have been two prominent chronic O_3 studies—an EPA 18-month chronic study fashioned after a realistic urban exposure profile with a peak exposure of 0.25 ppm (Chang et al., 1992; Costa et al., 1995) and the National Toxicology Program (NTP)—Health Effects Institute (HEI, 1994–1995) study of 0.125 to 1 ppm for 20 months (square wave; 6 h/day; 5 days/week). From an environmental relevance perspective, the $C \times T$ doses for these studies were similar, but the urban profile study produced evidence for centriacinar interstitial fibrosis consistent with earlier evidence of the influence of exposure pattern. There was no general biochemical evidence for fibrosis, as reported in monkey and rat studies that had been conducted at higher O_3 concentrations, perhaps due to the focal nature of the pathology. If one attempts to compare these results with the classic Cincinnati beagle study, one finds that the synthetic smog atmosphere showed degenerative and not fibrotic lung lesions. However, it should be noted that the air pollutant mixture in the beagle study involved more than O_3, was more complex, and had pollutants at significantly higher levels.

Paradoxically, O_3 has the ability to induce tolerance to itself and is a curious phenomenon in light of pathologies seen in episodic and chronic exposures. Classic O_3 tolerance takes the form of protection against a high or even lethal dose in rodents that has a pre-exposure to a very low initial challenge(s) several days before. This term, *tolerance*, is sometimes used to describe "adaptation" or acclimatization with repeated exposures to near-ambient levels of O_3, and as such, has led to some confusion. However, with regard to "adaptation" to O_3, the process begins during and immediately after the initial exposure and is fully expressed in 2 to 4 days. This adaptive phenomenon has been substantiated in humans with regard to diminished lung function and correlative inflammatory endpoints (Devlin et al., 1993). Lavage lactate dehydrogenase (LDH; a marker of cell injury) and elastase (enzymatically active against lung matrix material), interestingly, did not appear to adapt in one study carried out over 2 weeks in humans. An analogous pattern of adaptation of functional and biochemical endpoints (including LDH and elastase) also takes place in rodents with repeated exposures up to a week. But to date, the linkages between acute, adaptive, and long-term processes remain unclear, because both pathology and lung dysfunction do develop over longer periods of exposure in animals. The precise mechanism for O_3 adaptation is not known and several theories abound, including changes in cell profiles, lung surface fluids, and induced antioxidants. Few studies have tackled the problem but in rats the adaptation of the neutrophilic response appears to be related to the induction of an endogenous acute-phase response (McKinney et al., 1998). However, adaptation to lung function changes in rats after chronic exposure appears linked to lung antioxidants such as ascorbic acid (Wiester et al., 2000). The human relevance of this finding is uncertain because ascorbic acid is not endogenously synthesized as it is in the rat. However, self-administration of ascorbate has been shown to reduce O_3-induced lung function decrements in adults (Mudway et al., 1999), while in

runners it did not enhance performance (Gomes et al., 2011). Yet in children, supplementation with ascorbate and α-tocopherol lessened nasal inflammatory responses to O_3 in Mexico City (Sienra-Monge et al., 2004). Despite these interesting findings, it remains unclear whether antioxidant supplements can protect humans from long-term O_3 consequences given the many mechanisms that may be involved in the various responses. How supplementation may interplay with long-term adaptation and the likelihood of degenerative disease prevention is unclear.

Ozone Interactions with Co-pollutants The effects of O_3 may be altered by co-pollutants in the mixture or may otherwise interact to yield a novel composite outcome. How such interactions can be studied is often debated. Smog exposures are often difficult to deductively disassemble into a comprehensible configuration. However, one approach simplifying the complexity of smog, yet addressing the issue of pollutant interactions involves a bottom-up assembly of likely interacting pollutants. The exposures of animals or humans may be to binary or "assembled" synthetic mixtures of pollutants that occur together in ambient air. As such, the most frequent combinations involve interactions of O_3 and NO_2 or O_3 and PM (e.g., ambient, sulfuric acid, or diesel particles). Not surprisingly, study designs involving temporal or spatial exposures add a level of complexity in interpretation that may or may not support either augmentation or antagonism of lung function impairment, lung pathology, or a host of other indices of injury. This complexity only emphasizes the need to carefully consider the myriad of factors that might affect outcomes as well as how the design compares to real-world exposures of concern.

Studies of O_3 mixed with PM also have shown either enhanced or antagonistic responses that varied with exposure design. Studies of human volunteers exposed acutely with exercise to O_3 and diesel exhaust particles showed enhanced deficits in lung function (Madden et al., 2014). Similarly, as noted above, field studies of children in camps and studies of asthma admissions in the Northeastern United States and in Canada suggested an interaction of acid aerosols and O_3 resulting in augmented functional deficits to a composite ambient summer haze. Allergic mice, however, showed reduced lung infiltration of inflammatory cells to the O_3 and diesel particle exposure, with no change in airways resistance; yet, airway hyperreactivity was increased (Farraj et al., 2010). Likewise, rabbits exposed intermittently for 1 year to an O_3 (0.1 ppm) and sulfuric acid (125 $\mu g/m^3$) mixture had a temporal shift in secretory cell number, increasing midway through the study and then decreasing—with no evidence of mucociliary clearance dysfunction (Schlesinger et al., 1992). Studies of highly complex atmospheres such as one study involving acid-coated carbon combined with O_3 at near-ambient levels similarly show varied evidence of interaction on lung function and macrophage receptor activity (Kleinman et al., 1999). Thus, as can be gleaned, the interpretability of any multicomponent study is dependent on its statistical design and the ability to either separate or determine the nature of the interacting variables. The bottom line is that interactions are highly dependent on the conditions of exposure, endpoints selected for study, and a host of other factors. As the number of interacting variables increases, so does the difficulty in interpretation. Given the challenge that it is indeed the complex mixture to which people are exposed that we wish to evaluate, creative toxicological approaches to understanding mixture responses will demand new systems perspectives if real progress is to be achieved (Mauderly, 2006).

Nitrogen Dioxide

General Toxicology Nitrogen dioxide, like O_3, is a deep lung irritant that can produce pulmonary edema if it is inhaled at high concentrations. It is a much less potent irritant and oxidant than O_3, but NO_2 can pose clear toxicological problems. Potential life-threatening exposure is a real-world problem for farmers, as near-lethal high levels of NO_2 can be liberated from fermenting fresh silage. Being heavier than air, the generated NO_2 and CO_2 displace air and oxygen at the base of silo and diffuse into closed spaces where workers can inadvertently get exposed to very high concentrations perhaps with depleted oxygen. Typically, shortness of breath rapidly ensues with exposures nearing 75 to 100 ppm NO_2, with delayed edema and symptoms of pulmonary damage. Not surprisingly, the symptoms are collectively termed "silo-filler's disease." NO_2 is also an important indoor pollutant, especially in homes with unventilated gas stoves or kerosene heaters (Spengler and Sexton, 1983) or, in developing countries, with the unvented burning of biomass fuels (Kumie et al., 2009). Under such circumstances, very young children and their mothers who spend considerable time indoors may be especially at risk. In general, indoor environments with NO_2 sources achieve concentrations far in excess of those observed outdoors at central monitoring sites. Peak levels of NO_2 near high traffic volume roadways can be several fold higher than away from roadways and are thus similar to peak levels observed indoors with unvented stoves (i.e., 0.2 to 0.5 ppm). Interestingly, protocols that simulate an urban (rush-hour) or household (cooking) patterns of 2 daily peak exposures superimposed on a low continuous background concentration have elicited effects in experimental animals that continuous exposure to NO_2 did not evoke, suggesting an important dependency on exposure profile. Among the common air pollutants, empirical studies of NO_2 have frequently shown greater effects with higher peak concentrations at equivalent $C \times T$ steady-state concentrations.

Although the distal lung lesions produced by acute NO_2 are similar among species, there exist differences in species sensitivity. Where direct comparison is possible, guinea pigs, hamsters, and monkeys appear more sensitive than rats, although comparative dosimetry information might explain some of this difference. As in the case of O_3, theoretical dosimetry studies indicate that NO_2 is deposited along the length of the respiratory tree, with preferential deposition in the distal airways. Not surprisingly, the pattern of damage to the respiratory tract reflects this profile: damage is most apparent in the terminal bronchioles, just a bit more proximal in the airway than is seen with O_3. At high concentrations, the alveolar ducts and alveoli are also affected, with type 1 cells again showing their sensitivity to oxidant challenge. In the airways of these animals, there is also damage to epithelial cells in the bronchioles, notably with loss of ciliated cells, as well as a loss of secretory granules in Clara cells. Thus, the pattern of injury of NO_2 is quite similar to that of O_3, although its potency is about an order of magnitude lower.

Pulmonary Function Effects Exposure of normal human subjects to concentrations of less than or equal to 4 ppm NO_2 for up to 3 hours produces no consistent effects on spirometry. However, a study has shown slightly enhanced airway reactivity with 1.5 to 2.0 ppm. Interestingly, ascorbic acid pretreatment of human subjects appeared to protect them from this hyperreactivity (Mohsenin, 1987). Whether asthmatics have a particular sensitivity to NO_2 is a controversial issue. A number of factors appear to be involved (e.g., exercise, inherent sensitivity of the asthmatic subject, and exposure method). Some studies have reported effects in some individuals at 0.2 ppm, which approximates an indoor level in a household with an unvented gas stove. Meta-analyses, which have incorporated the findings of many studies to achieve a weight-of-evidence perspective, support a heightened effect of NO_2 on asthmatics, but it's not clear if the observed small but statistically significant changes in

airway hyperresponsiveness in asthmatics exposed to NO_2 below 0.6 ppm are adverse. As for an appropriate animal model, only very high concentrations (10 ppm NO_2) invoke an irritancy response in guinea pigs (tachypnea); these levels are well above those a person probably would encounter in everyday life. However, NO_2 has been found to be associated with mortality in some time-series studies of air pollution attempting to tease out specific pollutant effects (focusing mainly on PM) (Gold et al., 2000; Samoli et al., 2006). These epidemiology studies have demonstrated that each 20 to 30 ppb increase in NO_2 results in a small but significant increase in acute cardiovascular and respiratory mortality. Similarly, NO_2 has been associated with increased hospital admissions and emergency room visits, but these epidemiology studies are confounded by the co-exposure to multiple pollutants. Thus, as stressed elsewhere, it is important that epidemiology studies results be interpreted with caution when considering causality and that controlled human exposure and animal studies be utilized, within ethical limits, to confirm the biologic plausibility of the effect of NO_2, or any other pollutant, on the cardiopulmonary system. This caution obviously extends to many recent studies that have consistently linked adverse health outcomes with living near high traffic volume roadways. Because of the many constituents present in the exhaust of both gas and diesel combustion engines, as well as their ever changing chemistry, it is unclear from these studies whether NO_2 is acting as a marker or surrogate for vehicular traffic rather than as an indication of a specific NO_2 effect. These studies have found correlates with cardiovascular deaths, which have raised new questions of the mechanisms by which pollutants might affect health in susceptible subgroups (Rosenlund et al., 2006). Nevertheless, NO_2 does appear as a reasonable proxy for traffic for both cancer and noncancer outcomes in epidemiological studies, although the true nature of the NO_2 role remains unclear (Faustini et al., 2014; Hamra et al., 2015).

Inflammation of the Lung and Host Defense Unlike O_3, NO_2 does not induce significant neutrophilic inflammation in humans at exposure concentrations encountered in the ambient outdoor environment. There is some evidence for bronchial inflammation after 4 to 6 hours at 2.0 ppm, which approximates the highest transient peak indoor levels of this oxidant. Exposures at 2.0 to 5.0 ppm have been shown to affect T lymphocytes, particularly $CD8^+$ cells and natural killer cells that function in host defenses against viruses. Although these concentrations may be high, epidemiologic studies variably show effects of NO_2 on respiratory infection rates in children, especially in indoor environments. Animal models, by contrast, have for years shown associations between NO_2 and bacterial infection (Gardner, 1984). As noted for other effects, the incidence of infection in exposed models appears to be governed more by the peak exposure concentration than by exposure duration. The effects are ascribed to suppression of macrophage function and clearance from the lung, in the form of suppressed bactericidal and/or motility functions of macrophages from rabbits exposed to 0.3 ppm for 3 days (Schlesinger, 1987). Similar effects have been reported in humans exposed to 0.10 ppm for 6.6 hours (Devlin et al., 1991).

Toxicological studies of the interaction of NO_2 with viruses also suggest enhanced infectivity. Squirrel monkeys infected with nonlethal levels of A/PR-8 influenza virus and then exposed continuously to 5 or 10 ppm NO_2 suffered high mortality rates (Henry et al., 1970). Other experiments suggest that exposure of squirrel monkeys for 5 months to 5 ppm NO_2 depresses the formation of protective antibodies against the A/PR-8 influenza virus. Controlled human studies with virus challenges, however, have been inconclusive, perhaps because of low subject numbers. One study showed decreased virus inactivation by alveolar macrophages recovered from four of nine subjects when cultured and exposed for 3.5 hours to 0.6 ppm NO_2 in vitro (Frampton et al., 1989). Thus, the potential for augmented risk of viral infection associated with NO_2 exposure remains unclear and suggests a role for underlying host susceptibility. This concern would be greatest for children, especially during seasonal use of unvented gas-heaters, who have less mature pulmonary immune function.

Chronic Effects Concern about the chronic effects of NO_2 stem from early observations that a continuous 30-day, 30-ppm exposure produces emphysema in hamsters. Whether the result of this continuous exposure scenario relates to cyclic human exposures at 1/100th that level is unclear. On the one hand, an 18-month study in rats exposed to an urban pattern of NO_2 in which a daily background of 0.5 ppm peaked at 1.5 ppm for 4 hours each day showed little ultrastructural damage to the distal lung (Chang et al., 1988). On the other hand, mice exposed for a year to a base level of 0.2 ppm NO_2 with a 1-hour spike of 0.8 ppm twice a day 5 days per week (Miller et al., 1987) displayed effects that differed between the base-only and peak-only exposure groups. The base level produced no effects, while the overlaid peaks induced slight functional impairment and augmented susceptibility to bacterial infection. Early studies (Ehrlich and Henry, 1968) showed that clearance of bacteria from the lungs is suppressed with 0.5 ppm NO_2 through 12 months of exposure. Interestingly, studies with a similar double diurnal peak design for NO_2, with NO used as a negative control, showed more pronounced effects of NO on alveolar septal remodeling than did NO_2 (Mercer et al., 1995). These and similar studies utilizing varied peak-plus-baseline NO_x exposures indicate the importance of exposure profile for at least this pollutant.

Other Oxidants

While a number of other reactive oxidants have been identified in photochemical smog, most are short-lived because of their reaction with co-pollutants. Peroxyacetyl nitrate (PAN), which is thought to be responsible for much of the eye-stinging activity of smog, is known to exist in smog situations. It is more soluble and reactive than O_3, and hence rapidly decomposes in mucous membranes before it can penetrate into the respiratory tract. The cornea is a sensitive target and is prominent in the burning/stinging discomfort often associated with oxidant smogs. A few studies with high levels of PAN have shown that it can cause lung damage and have mutagenic activity in bacteria, but it is not likely that these scenarios are relevant to ambient levels of PAN.

Carbon Monoxide

Carbon monoxide is classed toxicologically as a chemical asphyxiant because its toxic action stems from its formation of carboxyhemoglobin, preventing oxygenation of the blood for systemic transport. The fundamental toxicology of CO and the physiologic factors that determine the level of carboxyhemoglobin attained in the blood at various atmospheric concentrations of carbon monoxide are detailed in Chap. 11, "Toxic Responses of the Blood."

The normal concentration of carboxyhemoglobin (COHb) in the blood of nonsmokers is about 0.5%. This is attributed to endogenous production of CO from heme catabolism, yet higher levels can be found in nonsmokers who are regularly exposed to secondhand smoke from cigarettes. Blood COHb is a function of the concentration in air, the length of exposure, and the ventilation of the exposed individual. Uptake is said to be ventilation-limited, implying that virtually all the CO inspired in a breath is absorbed and bound to the available hemoglobin. Thus, continuous exposure of human subjects to 30 ppm CO leads to an equilibrium value of 5% COHb.

The Haldane equation is used to compute the COHb equilibrium under a given exposure situation. The equilibrium values generally are reached after 8 hours or more of exposure, but the time required to reach equilibrium can be shortened by physical activity.

Carbon monoxide emissions from automobiles have progressively decreased since the 1970s. Increased combustion efficiency and catalytic convertors have reduced emissions at the tailpipe by more than 98%. However, motor vehicles can still account for two-thirds of urban CO. Depending on the location in a community, traffic density, vehicle types and age, and the urban structure, CO concentrations can vary widely. Concentrations predicted inside passenger compartments of motor vehicles in downtown traffic were almost three times those for central urban areas and five times those expected in residential areas. Occupants of vehicles traveling on expressways had CO exposures somewhere between those in central urban areas and those in downtown traffic, whereas concentrations in underground garages, tunnels, and buildings directly over highways can still reach high levels but substantially less and slower to accumulate. But it must be kept in mind that there are many sources of CO—anywhere combustion is ongoing. Certainly both main and side-stream tobacco smoke are a source. Faulty home heating systems and mobile auxiliary heating sources emit CO which when used inappropriately (i.e., unventilated) can create life-threatening circumstances, and nowadays, these indoor exposures are the most significant CO threat to health with about 430 deaths a year in the United States.

No overt clinical human health effects have been demonstrated for COHb levels below 2%, while levels above 40% cause fatal asphyxiation. However, there is evidence that in some people COHb in the range of 2.0% to 2.4% can elicit acute cardiovascular effects. A 90-minute exposure to about 50 ppm CO would likely result in COHb levels of about 2.5%, with a resultant impairment of time-interval discrimination even in healthy subjects; at approximately 5% COHb, there is an impairment of other psychomotor faculties. At 5% COHb in nonsmokers (the median COHb value for smokers is about 5%), however, maximal exercise duration and maximal oxygen consumption are reduced (Aronow, 1981). Clear cardiovascular changes also may be produced by exposures sufficient to yield COHb in excess of 5%. These include increased cardiac output, arteriovenous oxygen difference, and coronary blood flow in patients without coronary disease. Decreased coronary sinus blood PO_2 occurs in patients with coronary heart disease, and this would impair oxidative metabolism of the myocardium. In the early 1990s, a series of studies in subjects with cardiovascular disease were conducted in several laboratories under the sponsorship of the Health Effects Institute (HEI) to determine the potential for angina pectoris when they exercised moderately with COHb levels in the range of 2% to 6% (Allred et al., 1989). The results of these studies indicate that premature angina can occur under these conditions but that the potential for the induction of ventricular arrhythmias remains uncertain.

Carbon monoxide has been implicated as a potentially important co-pollutant of PM with potential human health effects at low ambient concentrations. Independent CO effects have been reported in some epidemiological studies of ambient air pollution, but its singular role versus indicator role (for traffic) continues to be debated. The fact that effects noted in these studies are cardiovascular and involve angina and effects on EKG patterns lend credence to a role for CO in epidemiologic health outcomes. Other data from epidemiologic studies have shown a linkage between CO and some general CNS indices as well as birth outcomes. The sensitivity of newer analysis methods for these population studies are revealing previously unappreciated health effects. Among these are preterm births, cardiac birth defects, and infant mortality in the postnatal period. Moreover, toxicological studies with animals also suggest potential developmental risks.

Reducing CO emissions from motor vehicles is a major goal because of its high hazard—a colorless and odorless non-irritant—so technical combustion engineering advances are being pursued as well as changes in fuel formulations for specific seasonal conditions. For example, the introduction of gasoline oxygenates such as MTBE in the 1990s and other ether derivatives constitute attempts to enhance fuel combustion and reduce CO emissions. The experience with MTBE (as noted earlier) has led to such gasoline reformulations being approached with some caution with greater attention being placed on assessments of potential unexpected consequences. Biofuels, comprised primarily of ethanol at varied percentages, in gasoline or diesel fuel, are part of an effort to reduce fossil fuel consumption and enhance renewables. Another goal is reduction in emissions that deteriorate the atmosphere directly or indirectly but the data supporting this outcome remains inconclusive. Regardless, CO remains a toxic air pollutant both indoors (e.g., secondhand smoke and cook stoves) and outdoors (combustion engines), which merits considerable attention wherever there is combustion.

Hazardous Air Pollutants

Hazardous air pollutants (so-called air toxics or HAPs) represent an inclusive classification for air pollutants of anthropogenic origin that are generally of measurable quantity in the air, and are not covered in the so-called Criteria Pollutant list of the Clean Air Act (CAA) of 1970. They are covered under Section 112 of the CAA. For a variety of reasons, HAPs are regulated in the United States not by ambient concentration (due to their generally focal nature near sources or uneven national distribution, complexity of measurement) but rather by application of best available technology to emission reduction, followed with an assessment of residual risk with that which is released. As such, most exposure estimates for these pollutants are derived from emission inventories that are modeled into the National Air Toxics Assessment (U.S. EPA, 2016). The most recent NATA assessment (2015) used 2011 data on 180 of the 187 HAPs, plus diesel PM. The diverse nature of even 30 of the 187 HAPs (the so-called "dirty 30"—Table 31-6) complicates a general discussion of their toxicology because the group

Table 31-6

List of 30 Urban Air Toxics ("Dirty 30")

ACETALDEHYDE	DIOXIN	MERCURY COMPOUNDS
Acrolein	Propylene dichloride	Methylene chloride (dichloromethane)
Acrylonitrile	1,3-Dichloropropene	Nickel compounds
Arsenic compounds	Ethylene dichloride (1,2-dichloroethane)	Polychlorinated biphenyls (PCBs)
Benzene	Ethylene oxide	Polycyclic organic matter (POM)
Beryllium compounds	Formaldehyde	Quinoline
1,3-Butadiene	Hexachlorobenzene	1,1,2,2-Tetrachloroethane
Cadmium compounds	Hydrazine	Tetrachloroethylene (perchloroethylene)
Chloroform	Lead compounds	Trichloroethylene
Chromium compounds	Manganese compounds	Vinyl chloride

SOURCE: From U.S. EPA (2016).

includes various classes of organic chemicals (by structure, e.g., acrolein, benzene), minerals (e.g., asbestos), polycyclic hydrocarbon particulate material (e.g., benzo(*a*)pyrene), and various metals and metal compounds (e.g., mercury and beryllium compounds) and pesticides (e.g., carbaryl and parathion).

The focus to date on the HAPs has been on their potential carcinogenicity, as shown in chronic bioassays, mutagenicity tests in bacterial systems, structure–activity relationships, or—in a few special cases (e.g., benzene and asbestos)—their known carcinogenicity in humans. Hazardous air pollutant cancers need not be, and generally are not, simply pulmonary in origin. Details on the systemic carcinogenicity of many of these chemicals can be found elsewhere in this text or in the literature (Loh et al., 2007). However, noncancer issues frequently relate to direct lung toxicants that, upon accidental release or fugitive emission, might put at risk those susceptible (e.g., children) or who have preexisting disease (e.g., asthma or other chronic lung or cardiac disease). The assessment of noncancer risk to a given air toxic whether to the lung or other organ system is determined via the computation of long-term risk reference exposure concentrations (RfCs). This RfC is that concentration to which an individual may be exposed over a lifetime without adverse, irreversible injury. The official computational process to HAP assessment is discussed in detail at www.epa.gov/risk/review-reference-dose-and-reference-concentration-processes-document. This process remains hotly debated but attempts to use the latest and best data available to address potential risks to the diverse public. A short-term RfC method has been developed for exposures up to 30 days that is sometimes used to assess noncancer applications. In the NATA assessment of toxic inhalants, acrolein ranks as the top risk based on emission inventories, the potential for exposure, and its inherent irritancy. Discussion of this topic and an approach to mixed exposures to noncancer HAPs has been reviewed (Costa, 2003).

Accidental and "Fence-Line" Exposures

The relationship between the effects associated with an accidental release of a large quantity of a volatile chemical into the air from a point source such as a chemical plant and the effects associated with a chronic low-level exposure over many years or a lifetime is not clear. Regarding cancer risk, which typically defaults to a linearized model of dose and effect, the issue is fairly straightforward. Exposures must be minimized if not eliminated if cancer risk is to be kept as close to zero as possible. With noncancer risks, the roles of nonspecific or specific host defenses, thresholds of response, and repair and recovery after exposure complicate the assessment of risk. In large part, the issue here relates to a cumulative index, often a $C \times T$. Can we better relate disease or injury to a *cumulative dose* or a *peak* concentration for any given or a protracted exposure? Is there an exposure peak beyond which a cumulative approach fails (i.e., the effect is concentration driven), or is concentration always the dominant determinant? Many of these questions have yet to be answered, not to mention their specificity with regard to individual compounds and tissues affected.

Methyl isocyanate provides a contrast between the catastrophic effects of a large accidental release versus long-term effects linked to cyclic or continuous fugitive releases of small amounts of chemical vapor. The reactive nature of methyl isocyanate with aqueous environments is of such magnitude that upon inspiration, almost immediate mucous tissue corrosion can be perceived. The vapor undergoes hydrolysis within the mucous lining of the airways to generate hydrocyanic acid, which destroys the airway epithelium and causes acute bronchoconstriction and edema. The damage is immediately life-threatening at concentrations above 50 ppm; at 10 ppm, it is damaging in minutes. These concentrations are in the range of the dense vapor cloud that for several hours in 1984 enshrouded the village of Bhopal (India) bordering a Union Carbide pesticide plant. Studies in guinea pigs have shown the immediate irritancy of this isocyanate, which in just a few minutes also results in significant pathology (Alarie et al., 1987). Rats exposed to 10 or 30 ppm for 2 hours also showed severe airway and parenchymal damage, which did not resolve in surviving rats; transient effects were seen at 3 ppm. Even 6 months after exposure, the airway and lung damage remained, having evolved into patchy, mostly peribronchial fibrosis with associated functional impairments (Stevens et al., 1987). There was also cardiac involvement secondary to the damage to the pulmonary parenchyma and arterial bed (i.e., pulmonary hypertension and right-sided heart hypertrophy). This same spectrum of health effects has resulted in disability and the deaths of thousands of initial survivors since the incident.

In the United States, methyl isocyanate has been measured in the ambient air in Katawba Valley, Texas, as a result of small but virtually continual fugitive releases of the vapor into the community air ("fence-line") from an adjoining region with several chemical plants. While these levels of methyl isocyanate are not sufficient to cause the damage seen in Bhopal, there is concern that low-level exposure over many years may have more diffuse, chronic effects. Residents complain of odors and a higher frequency of respiratory disorders, but clear evidence of injury or disease is lacking. Fence-line exposures to a variety of industrial chemicals remain a significant potential risk for many communities—often low-income or worker communities near one or more industrial sources. Silent continuous or periodic releases from pipelines or transfer points within facilities can disperse through communities unbeknownst to anyone. The advent of newer sensor technologies and better conduit systems for process operations is slowly reducing risks in more advanced nations but the exposure risks remain high elsewhere.

Phosgene is best known for its use as a war gas, but it is also a common intermediate reactant used in the chemical industry, particularly in pesticide formulation, and subject to accidental or low-level fugitive releases. Because of its direct pulmonary reactivity, it lends itself to use as a model pulmonary toxicant for studies addressing $C \times T$ relationships that can inform assessment of risk under varied exposure patterns. These studies suggest that there may be a threshold below which compensatory and other bodily defenses (e.g., antioxidants) may be able to cope perhaps with long-term low-level tolerance, although as with O_3 there is evidence of mild interstitial fibrosis. In rat studies, this threshold for acute toxicity for phosgene appears to be at or below the current threshold limit value of 0.1 ppm for 8 hours, which suggests little or no margin of safety for workers. At higher concentrations, however, peaks in concentration (C) appear to be the primary determinants of injury triggering disease with duration of exposure being less important to the injury process. There can be some adaptation with time, but there is not sufficient recovery and hence the lesion appears to be a concentration-driven response exceeding that predicted arithmetically by $C \times T$. This relationship appears to be different from that of acute exposures to O_3 at ambient levels, which can be approximated by the $C \times T$ paradigm. Hence, the $C \times T$ concept for lung injury appears to function best at low ambient levels and less well for event exposures such as in accidents.

Aldehydes

Among the HAPs that have broader exposure potential for the public, two aldehydes capture attention for their toxicity/irritancy and their ubiquity. These two aldehydes are formaldehyde (HCHO) and

acrolein ($H_2C{=}CHCHO$). As carbonyl compounds, they are short-chained (2 to 4 C) and are generated as photo-oxidation products of unsaturated hydrocarbons in the outdoor air, and as common intermediates in chemical reactions, they can arise in the indoor environment. Formaldehyde accounts for about 50% of the estimated total aldehydes in polluted air, while acrolein, the more irritating of the two, accounts for about 5% of the total. Other aldehydes, such as acetaldehyde (C_3HCHO) and many other longer-chain aldehydes, make up the remainder, but they are not as intrinsically irritating, exist at low concentrations, and have less solubility in airway fluids. Formaldehyde and particularly acrolein are also found in mainstream tobacco smoke (about 90 and about 8 ppm, respectively, per puff) and side-stream smoke as well. Formaldehyde is also an important indoor air pollutant and can often achieve higher concentrations indoors than outdoors due to off-gassing by new upholstery or other furnishings. In the United States, the formaldehyde off-gassing issue was highlighted in the controversy surrounding the trailer homes provided to hurricane-displaced home owners post-hurricane Katrina.

Empirical studies have shown that formaldehyde and acrolein are competitive agonists for similar irritant receptors in the airways. Thus, irritation may be related not to "total aldehyde" concentration but to specific ratios of acrolein and formaldehyde. Their relative difference in solubility, with formaldehyde being somewhat more water-soluble and thus having more nasopharyngeal uptake, may distort this relationship under certain exposure conditions (e.g., exercise). However, acrolein is very reactive and may interact easily with many tissue macromolecules and, for example, can form DNA adducts.

Formaldehyde

Formaldehyde is a primary sensory irritant. Because it is very soluble in water, it is absorbed in mucous membranes in the nose, upper respiratory tract, and eyes. The concentration–response curve for formaldehyde is steep: 0.5 to 1 ppm yields a detectable odor; 2 to 3 ppm produces mild irritation; and 4 to 5 ppm is intolerable to most people. Formaldehyde is thought to act via sensory C-fibers that signal locally as well as through the trigeminal nerve to reflexively induce bronchoconstriction through the vagus nerve. In guinea pigs, a 1-hour exposure to about 0.3 ppm of formaldehyde induces an increase in airflow resistance accompanied by a decrease in compliance (Amdur, 1960). The no observed effect level (NOEL) using these lung function criteria is about 0.05 ppm. The general pattern of the irritant response and its rapid recovery is similar to that produced by higher concentrations of the irritant, SO_2.

Two aspects of formaldehyde toxicology have brought it from relative obscurity to the forefront of attention in recent years. One is its near ubiquitous presence in indoor atmospheres as an off-gassed product of construction materials such as plywood, furniture, or improperly polymerized urea–formaldehyde foam insulation. In studies relating household formaldehyde levels to chronic effects, children were found to have significantly lower peak expiratory flow rates (about 22% in homes with 60 ppb) than did unexposed children, and asthmatic children were affected below 50 ppb. Also, there is epidemiologic evidence that links formaldehyde to asthma (McGwin et al., 2010) and an increase in lower respiratory tract infections in children (Roda et al., 2011).

A longtime concern regarding formaldehyde has been its potential carcinogenicity. In 2004, IARC concluded that formaldehyde was a "probable human carcinogen" based on evidence of nasopharyngeal cancer and possibly leukemia—based on animal studies (Cogliano, 2005). Nasal cancer had been induced empirically with formaldehyde vapor in a 2-year study where rats were exposed to 2, 6, or 14 ppm 6 hours per day, 5 days per week. Mice were much less sensitive than rats. The detection of DNA adducts in the noses of the two species paralleled the difference in the incidence of tumors. However, the risk associated with exposure to formaldehyde remains controversial because of its widespread industrial use. The reader is encouraged to sample the recent literature (e.g., Nielsen et al., 2017).

Acrolein

Because acrolein is an unsaturated aldehyde, it is more reactive than formaldehyde. It penetrates a bit deeper into the airways and may not have the same degree of sensory irritancy but it may cause more cellular damage. Concentrations below 1 ppm cause irritation of the eyes and the mucous membranes of the respiratory tract. Exposure of guinea pigs to more than or equal to 0.6 ppm reversibly increased pulmonary flow resistance and tidal volume and decreased respiratory frequency (Murphy et al., 1963). The mechanism of increased resistance appears to be mediated through a both local C-fiber and centrally mediated cholinergic reflexes (Bessac and Jordt, 2010).

Exposures of rats to 0.4, 1.4, or 4.0 ppm acrolein for 6 hours per day, 5 days per week for 13 weeks resulted in paradoxical effects on lung function (Costa et al., 1986). The lowest concentration resulted in hyperinflation of the lung with an apparent reduction in small-airway flow resistance, while the highest concentration resulted in airway injury and peribronchial inflammation and fibrosis. The intermediate concentration was functionally not different from the control, although airway pathology was evident. It appears that the high-concentration response reflected the cumulative irritant injury and remodeling as a result of the repeated acrolein, while the low-concentration group had little overt damage and appeared to have slightly stiffened airways, perhaps a result of the protein cross-linking action of acrolein. The pathology in these rats contrasts with that found in formaldehyde studies of similar duration where only upper airway involvement was observed. Ambient exposure to acrolein probably would be about 10% to 20% of the low concentration used in the subchronic study discussed above. Because of a lack of sufficient human data, these animal data were used to perform a risk assessment analysis which showed an excess risk to humans for the adverse effect of ambient levels of acrolein on pulmonary function (Woodruff et al., 2007). Ambient concentrations of acrolein are well below those found in mainstream and secondhand tobacco smoke and occupational exposure levels. As reviewed elsewhere (Bein and Leikauf, 2011; Henning et al., 2017), acrolein produces a wide range of adverse pulmonary effects including lung cancer that may be linked mechanistically to *p53* (a tumor suppressor gene) DNA adducts and mutations, as well as cardiovascular effects.

Thus, as a class the aldehydes can be very irritating and may constitute a significant fraction of the discomfort and sensation experienced during an oxidant pollution episode, especially in mixed atmospheres containing particles.

THE MULTIPOLLUTANT REALITY OF AIR POLLUTION

The pollutant profiles of any community's atmosphere vary considerably in space and time. These pollutants are emitted locally and are mixed with pollutants transported over varied distances while undergoing photochemical transformation—hence the phrase: "urban soup." For decades, these complexities have been daunting for toxicologists, and therefore scientists and risk assessors are

prompted to adopt a reductionist approach—evaluating nominally one pollutant at a time. While the reductionist approach has been very successful in providing data to target pollutants of primary concern and improving public health, it is widely thought that there are likely chemical and physiological interactions between and among pollutants that are of public health consequence, but have not been appreciated. Indeed, interactions are more likely to be apparent as exposure concentrations decrease, and while we may be concerned about synergistic interactions as found with some particles and SO_2, it may be that antagonisms also occur among pollutants that are prevalent. As the science and the statistical methods to look at interactions have improved, there is renewed interest in multipollutant toxicology.

Publications are revisiting this issue (Mauderly and Samet, 2009; Buckley and Farraj, 2015; Davalos et al., 2017), where scientists from all sectors are trying to determine whether there are better approaches to studying interactions (Dominici et al., 2010; Vedal and Kaufman, 2011), synthesizing or modeling findings to extract interactions (Johns et al., 2012), and then translating and implementing the findings to reduce the components or factors central to mixture behavior in terms of health risk (Fann et al., 2011). There is yet to be consensus on approaches and most likely there will be more than one approach; however, the advances in the science and evolution of the air pollution scenario to one of lower background and dominant source contributors suggests that novel thinking is needed on this issue. Early toxicology studies that were focused on complex mixtures, some of which were photochemically altered (discussed earlier), along with epidemiology studies usually came to conclusions relevant to that mixture alone. But the revival of the PM story, and that it is itself a mixture of trace elements and organic and elemental carbon, has raised questions about the mix of key PM attributes that drive outcomes and how co-pollutants interplay in these outcomes. While single pollutant approaches to air pollution research, health assessments, and ambient air quality standard setting have been successful in reducing global air pollution over past decades, there is a clear need for novel ideas to address this next dimension of air quality management via scientific and regulatory/policy innovation.

CONCLUSIONS

In writing this textbook chapter on air pollution toxicology, the authors' goal has been to relate empirical studies in animals as well as controlled studies in humans to provide biologic plausibility to health observations revealed or described through epidemiology. The breadth and complexity of the problem of air pollution—from the development of credible databases to utilizing these data sources to inform regulatory action and decision making—have been the theme throughout the chapter. The classical and still most prominent air pollutants provide a foundation for understanding and appreciating the nuances and dissecting outcomes upon which defensible air pollution policy and decision making can be applied to public health. The key role of the toxicologist is to ask questions to provide understanding while developing sensitive and relevant assay methods. An understanding of air pollution exposure as well as basic biology is key to revealing the causality information needed to support decision making hand-in-hand with epidemiology.

ACKNOWLEDGMENTS

What is there that is not poison? All things are poison and nothing without poison. Solely the dose determines that a thing is not a poison.

—Paracelsus

It is impossible to consider the topic of forensic toxicology without discussing analytical toxicology in detail, as analytical toxicology has its roots in forensic applications. Therefore, it is logical to discuss these mutually dependent areas together. Analytical toxicology involves the application of the tools of analytical chemistry to the qualitative and/or quantitative estimation of chemicals that may exert effects on living organisms. Generally, the chemical that is to be measured (the analyte) is a xenobiotic that may have been altered or transformed by metabolic actions of the organism. Frequently, the specimen that is to be analyzed consists of a matrix composed of body fluids or solid tissues removed from the organism. Both the identity of the analyte and the complexity of the matrix can present formidable problems to an analytical toxicologist.

Forensic toxicology involves the use of toxicology for the purposes of the law (Cravey and Baselt, 1981). Although this broad definition includes a wide range of applications, such as regulatory toxicology and workplace urine testing to detect drug use, by far the most common application is to identify any chemical that may serve as a causative agent in inflicting injury or death on humans, or in causing damage to property. Frequently, as a result of such unfortunate incidents, charges of liability or criminal intent are brought that must be resolved by the judicial system. At times, indirect or circumstantial evidence is presented in an attempt to prove cause and effect. However, there is no substitute for the unequivocal identification of a specific chemical substance that is demonstrated to be present in tissues from the victim at a sufficient concentration to explain the injury with certainty. For this reason, forensic toxicology and analytical toxicology have long shared a mutually supportive partnership.

To aid in deciding whether adverse effects of xenobiotics contribute to death, injury, or other harm to persons or property, great efforts are made to initiate and implement analytical procedures in a forensically credible manner. Laws prescribing punishment to drug-impaired drivers are evidence of attempts to mitigate impaired driving. The measurement of ethanol in blood or breath at specific concentrations is generally required to prove impairment by this agent (Fisher et al., 1968). Similarly, the decade of the 1980s saw a growing response by society to the threat of drug abuse. Identification of drug users through testing urine for the presence of drugs or their metabolites, using methods and safeguards developed by forensic toxicologists, has become required by law (Department of Health and Human Services, 1988).

The diagnosis and treatment of health problems induced by chemical substances and the closely allied field of therapeutic drug monitoring also rely greatly on analytical toxicology. Although the analytes are present in biological matrices similar to those obtained for traditional forensic toxicology, the results must be reported rapidly to be of use to clinicians in treating patients. This requirement of a rapid turnaround time often limits the number of chemicals that can be measured because analytical methods, equipment, and personnel must all be available for a swift response to toxicological emergencies. More recently, analytical toxicology methods have also been employed for the detection of drugs and other chemicals used for the purpose of performance-enhancement, which can also require rapid reporting in selected settings, including athletic events.

Occupational toxicology and regulatory toxicology also require analytical procedures for their implementation or monitoring. In occupational toxicology, the analytical methods used to monitor threshold limit values and other criteria for estimating the exposure of workers to toxic hazards may utilize simple, nonspecific, but economical screening devices. However, to determine the actual exposure of a worker, it is necessary to analyze blood, urine, breath, or another specimen by employing methods similar to those used in clinical or forensic toxicology. For regulatory purposes, a variety of matrices (e.g., food, water, and air) must be examined for

extremely small quantities of analytes. Frequently, this requires the use of sophisticated methodology with extreme sensitivity. Both of these applications of analytical toxicology impinge on forensic toxicology because an injury or occupational disease in a worker can result in a legal proceeding, as well as can occur with a violation of a regulatory law.

Other applications of analytical toxicology occur frequently during the course of experimental studies. Confirmation of the concentration of dosing solutions and monitoring of their stability often can be accomplished with the use of simple analytical techniques. The bioavailability of a dose may vary with the route of administration and the vehicle used. Blood concentrations can be monitored as a means of establishing this important parameter. In addition, an important feature in the study of any toxic substance is the characterization of its metabolites as well as the distribution of the parent drug, together with its metabolites, to various tissues. This requires sensitive, specific, and valid analytical procedures. Similar analytical studies can be conducted within a temporal framework to gain an understanding of the dynamics of the absorption, distribution, metabolism, and excretion of toxic chemicals.

It is evident that analytical toxicology is intimately involved in many aspects of experimental and applied toxicology. Because toxic substances include all chemical types and the measurement of toxic chemicals may require the examination of biological or nonbiological matrices, the scope of analytical toxicology is broad. Nevertheless, a systematic approach and a reliance on the practical experience of generations of forensic toxicologists can be used in conjunction with the sophisticated tools of analytical chemistry to provide the data needed to better understand the hazards of toxic substances.

ANALYTICAL TOXICOLOGY

In light of the statement by Paracelsus five centuries ago, "All substances are poisons: there is none which is not a poison," analytical toxicology potentially encompasses all chemical substances. Forensic toxicologists learned long ago that when the nature of a suspected poison is unknown, a systematic, standardized approach must be used to identify the presence of most common toxic substances. An approach that has stood the test of time was first suggested by Chapuis in 1873 in *Elements de Toxicologie*. It is based on the origin or nature of the toxic agent (Petersen et al., 1923). Such a system can be characterized as follows:

1. Gases
2. Volatile substances
3. Corrosive agents
4. Metals
5. Anions and nonmetals
6. Nonvolatile organic substances
7. Miscellaneous

Closely related to this descriptive classification is the method for separating a toxic agent from the matrix in which it is embedded. The matrix is generally a biological specimen such as a body fluid or tissue. The agent of interest may exist in the matrix in a simple solution or may be bound to protein and other cellular constituents. The challenge is to separate the toxic agent in sufficient purity and quantity to permit it to be characterized and quantified. At times, the parent compound is no longer present in large enough amounts to be separated. In this case, known metabolites may indirectly provide a measure of the parent substance (Hawks and Chiang, 1986). With other substances, interaction of the poison with tissue components may require the isolation or characterization of a protein adduct (San George and Hoberman, 1986; Stockham and Blanke, 1988). Methods for separation have long provided a great challenge to analytical toxicologists. Over the previous 20 years, improved methods have become available that permit direct measurement of some analytes without prior separation from the matrix.

Gases are most simply measured by means of gas chromatography. Some gases are extremely labile, and the specimen must be collected and preserved at temperatures as low as that of liquid nitrogen. Generally, the gas is carefully liberated by incubating the specimen at a predetermined temperature in a sealed container. The gas, freed from the matrix, collects in the empty "headspace" between the specimen and the sealed container, where it can be sampled and injected into the gas chromatograph. Other gases, such as carbon monoxide, interact with proteins. These gases can be carefully released from the protein, or the adduct can be measured independently, as in the case of carboxyhemoglobin.

Volatile substances are generally liquids of a variety of chemical types. The temperature at which they boil is sufficiently low such that older methods of separation employed microdistillation or diffusion techniques. Gas chromatography is the simplest approach for simultaneous separation and quantitation of volatile substances. The simple alcohols (e.g., ethanol) can be measured by injecting a diluted body fluid directly onto the analytical column of the gas chromatograph. A more common approach is to use the headspace technique, as is done for gases, after incubating the specimen in a sealed vial at an elevated temperature.

Corrosives include mineral acids and bases. Many corrosives consist of ions that are normal tissue constituents. Clinical chemical techniques can be applied to detect these ions when they are in great excess over normal concentrations. Because these ions are endogenous constituents, the corrosive effects at the site of contact of the chemical, together with other changes in blood chemistry values, can confirm the ingestion of a corrosive substance.

Metals are encountered frequently as occupational and environmental hazards. Elegant analytical methods are available for most metals even when they are present at extremely low concentrations. Classic separation procedures involve destruction of the organic matrix by chemical or thermal oxidation. This leaves the metal to be identified and quantified in the inorganic residue. Unfortunately, this prevents the determination of the metal in the oxidation state or in combination with other elements, as it existed when the metal compound was absorbed. For example, the toxic effects of metallic mercury, mercurous ion, mercuric ion, and dimethylmercury are all different. Selected analytical methods must be capable of determining the speciation and relative amount of each form present to interpret the degree of toxicity. The analytical difficulty in doing so has resulted in the unfortunate practice of describing the toxicity of metals as if each metal existed as a single entity.

Toxic anions and nonmetals present an analytical challenge. With the exception of phosphorus, these agents are rarely encountered in an uncombined form. Some anions can be trapped in combination with a stable cation, after which the organic matrix can be destroyed, as with metals. Others can be separated from the bulk of the matrix by dialysis, after which they are detected by colorimetric or chromatographic techniques. Still others are detected and measured by ion-specific electrodes.

The *nonvolatile organic substances* constitute the largest group of substances that must be considered by analytical toxicologists. This group includes drugs, both prescribed and illicit, pesticides, natural products, pollutants, and industrial compounds. These substances are solids or liquids with high boiling points. Thus, separation procedures generally rely on differential extractions of biological

fluids and tissues (Fig. 32-1). These extractions often are inefficient, and recovery of the analyte from the matrix may be poor. When the nature of the analyte is known, immunoassay procedures, if available, are useful because they allow a toxicologist to avoid using separation procedures. These compounds can be classified as follows:

1. Organic strong acids
2. Organic weak acids
3. Organic bases
4. Organic neutral compounds
5. Organic amphoteric compounds

Separation of the classes specified above is generally achieved by adjusting the acidity of the aqueous matrix and extracting with a water-immiscible solvent or a solid-phase sorbent material. Finally, a *miscellaneous* category must also be included to cover the large number of compounds that cannot be detected by the routine application of the methods described above. Venoms and other toxic mixtures of proteins, or uncharacterized constituents, fall into this class. Frequently, if antibodies can be produced against the active constituent, an immunoassay may be the most practical means of detecting and measuring these highly potent and difficult-to-isolate substances. Unfortunately, unless highly specific monoclonal antibodies are used, the analytical procedure may not be acceptable for forensic purposes. Most frequently, specific analytical procedures must be developed for each analyte of this type. At times, biological endpoints are utilized to semiquantify the concentration of the isolated product.

ROLE IN GENERAL TOXICOLOGY

In almost all experimental studies in toxicology, an agent, generally a single chemical substance is administered in known amounts to an organism. It is universally acknowledged that the chemical under study must be either pure, or the nature of any contaminant well-characterized, to enable interpretation of the experimental results with validity. However, it is a common practice to proceed with the experimental study without verifying the identity and purity of the compound. Not only does this practice lead to errors in establishing an accurate dose, but also, depending on the nature of the study, other erroneous conclusions may be drawn. For example, the presence of related compounds in the dosage form of a tricyclic antidepressant led to erroneous conclusions about the metabolic products of the drug when it was administered together with the unidentified contaminants (Saady et al., 1981). An even greater error may result when a small amount of a contaminant may be supertoxic. A well-publicized

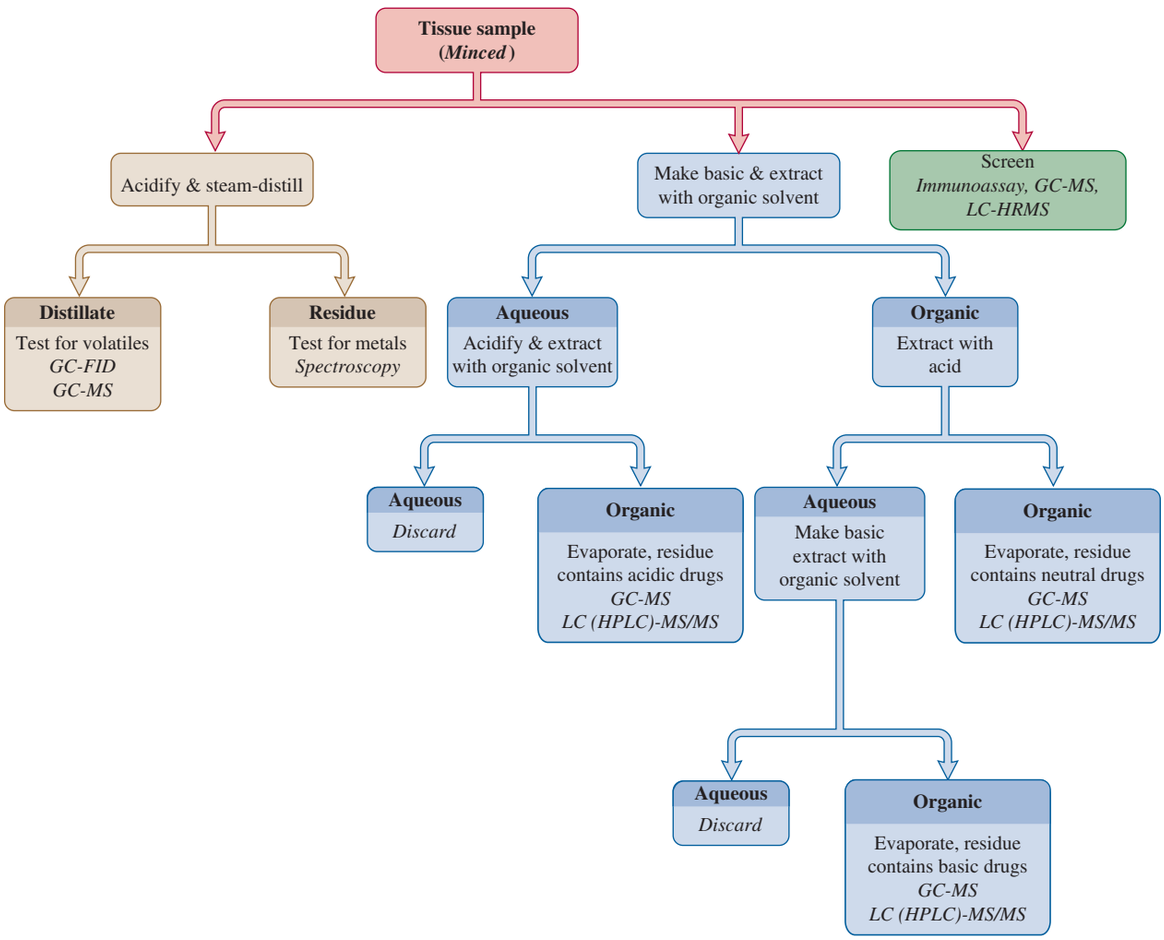

Figure 32-1. *A scheme of separation for poisons from tissues.*

example of this error involved the presence of dioxin in mixtures of the defoliants 2,4-D and 2,4,5-T (Panel on Herbicides, 1971) used during the Vietnam War as Agent Orange. Some of the adverse effects of Agent Orange are considered to be due to the low concentration of dioxin in those mixtures. Other researchers have reported that the toxicity of mixtures of polybrominated biphenyls may be due to the high toxicity of specific components, whereas other brominated biphenyls are relatively nontoxic (Mills et al., 1985).

A related application of analytical toxicology is the monitoring of dosage forms or solutions for stability throughout the course of an experimental study. Chemicals may degrade when in contact with air, by exposure to ultraviolet or other radiation, by interaction with constituents of the vehicle or dosing solution, and by other means. Developing an analytical procedure by which these changes can be recognized and corrected is essential in achieving consistent and reliable results over the course of a study (Blanke, 1987; Peters et al., 2007).

Finally, analytical methods are necessary to determine the bioavailability of a compound that is under study. Some substances with low water solubility are difficult to introduce into an animal, and a variety of vehicles may be investigated. However, a comparison of the blood concentrations for the compound under study provides a simple means of comparing the effectiveness of vehicles. Introducing a compound into the stomach in an oil vehicle may not be the most effective means of enhancing the absorption of that compound (Granger et al., 1987). Rather than observing dose–effect relationships, it may be more accurate to describe blood (or serum) concentration–effect relationships.

ROLE IN FORENSIC TOXICOLOGY

The duties of a forensic toxicologist in postmortem investigations include the qualitative and quantitative analysis of drugs or poisons in biological specimens collected at autopsy and the interpretation of the analytical findings with respect to the physiological and behavioral effects of the detected chemicals on the deceased at the time of injury and/or death.

The complete investigation of the cause or causes of sudden death is an important civic and legal responsibility. The responsibility of establishing the cause of death rests with the medical examiner or coroner, but success in arriving at the correct conclusion often depends on the combined efforts of the pathologist and the toxicologist. The cause of death in cases of poisoning cannot be proved beyond contention without toxicological analysis that confirms the presence of the toxicant in either body fluids or tissues of the deceased.

Many drugs or poisons do not produce characteristic pathological lesions; their presence in the body can be demonstrated only by chemical methods of isolation and identification. If toxicological analyses are limited, deaths resulting from poisoning may be erroneously ascribed to an entirely different cause or poisoning may be designated as the cause of death without empirical proof. Thus, limiting analysis may have significant legal and social consequences.

Additionally, a toxicologist can furnish valuable evidence concerning the circumstances surrounding a death. Such cases commonly involve demonstrating the presence of intoxicating concentrations of ethanol in victims of automotive or industrial accidents, or measurements of concentrations of carbon monoxide in fire victims. Arson may be used to conceal homicide. The degree of carbon monoxide saturation of the blood may indicate whether the deceased died as a result of the fire or was dead before the fire started. Also, licit or illicit psychoactive drugs often play a significant role in the circumstances associated with sudden or violent death. The behavioral toxicity of many illicit drugs may explain the bizarre or "risk-taking" behavior of the deceased that led to his or her demise. At times, a negative toxicological finding is of particular importance in assessing the cause of death. For example, toxicology studies may demonstrate that a person with a seizure disorder was not taking the prescribed medication and that this noncompliance contributed to the fatal event.

Additionally, the results of postmortem toxicological testing provide valuable epidemiological and statistical data. Forensic toxicologists are often among the first to alert the medical community to new epidemics of substance abuse (Poklis, 1982) and the dangers of abusing over-the-counter drugs (Garriott et al., 1985). Similarly, they often determine the chemical identity and toxicity of novel analogs of psychoactive agents that are subject to abuse, including "designer drugs" such as "china white" (methylfentanyl) (Henderson, 1988), "ecstasy" (methylenedioxymethamphetamine) (Dowling et al., 1987), and GHB (gamma-hydroxybutyric acid) (Andresen et al., 2011). Subsequently, several newer groups of designer drugs, including the synthetic cathinones and derivatives such as 4-methylmethcathinone (mephedrone) and methylone (Cawrse et al., 2012; Prosser and Nelson, 2012), 3,4-methylenedioxypyrovalerone and 5,6-methylenedioxy-2-aminoindane (MDAI) (Coppola and Mondola, 2012; Gallagher et al., 2012; Ross et al., 2012), and products containing synthetic cannabinoids, such as "K2" and "Spice" (Seely et al., 2012), among others, have emerged as new trends, particularly among young age groups (Rosenbaum et al., 2012). More recently, the increasing abuse of fentanyl, fentanyl analogs, and other synthetic opioids (Table 32-1) became a serious threat to the public health. Fentanyl is a synthetic opioid 50 to 100 times more potent than morphine, and carfentanil is a fentanyl analog estimated to be 10,000 times more potent morphine. These highly potent synthetic opioids contributed to

Table 32-1

List of Fentanyl Analogs and Other Synthetic Opioids Reported

FENTANYL ANALOGS	OTHER SYNTHETIC OPIOIDS
Acetylfentanyl	AH-7921
Acrylfentanyl	MT-45
4-ANPP	U-47700
Butyrylfentanyl	U-49900
Carfentanil	U-50488
Cyclopropylfentanyl	
ortho-Fluorofentanyl	
para-Fluorobutyryl fentanyl (FIBF)	
para-Fluorofentanyl	
Furanylfentanyl	
Isobutyrylfentanyl

4-Methoxybutyrylfentanyl	
4-Methylphenethylacetylfentanyl	
3-Methylfentanyl	
Beta-hydroxythiofentanyl	
Valerylfentanyl	

approximately 20,000 overdose deaths in 2016, a fivefold increase from 3105 deaths in 2013 (O'Donnell et al., 2017).

Today, there are numerous specialized areas of study in the field of toxicology; however, it is the forensic toxicologist who is obliged to assist in the determination of the cause of death for a court of law and who has been historically recognized by the title "toxicologist."

Until the 19th century, physicians, lawyers, and law enforcement officials harbored extremely faulty notions about the signs and symptoms of poisoning (Thorwald, 1965). Unless a poisoner was literally caught in the act of the crime, there was no way to establish whether the victim died from poisoning. In the early 18th century, a Dutch physician, Hermann Boerhoave, theorized that various poisons in a hot, vaporous condition yield characteristic odors. He placed substances suspected of containing poisons on hot coals and evaluated their smells. Although Boerhoave was not successful in applying his method, he was the first to suggest a chemical method for proving the presence of poison.

White arsenic (arsenic trioxide) has been widely used with murderous intent for over a thousand years. Therefore, it is not surprising that the first milestones in the chemical isolation and identification of a poison in body tissues and fluids were described for arsenic. In 1775, Karl Wilhelm Scheele, a Swedish chemist, discovered that white arsenic is converted to arsenous acid by chlorine water. The addition of metallic zinc reduced the arsenous acid to poisonous arsine gas. If gently heated, the evolving gas would deposit metallic arsenic on the surface of a cold vessel. In 1821, Serullas utilized the decomposition of arsine for the detection of small quantities of arsenic in stomach contents and urine in poisoning cases. In 1836, James M. Marsh, a chemist at the Royal British Arsenal in Woolwich, applied Serullas' observations in developing the first reliable method to determine the presence of an absorbed poison in body tissues and fluids such as liver, kidney, and blood. After acid digestion of the tissues, Marsh generated arsine gas, which was drawn through a heated capillary tube. The arsine decomposed, leaving a dark deposit of metallic arsenic. Quantitative measures were performed by comparing the length of the deposit from known concentrations of arsenic with those of the test specimens.

The 1800s witnessed the development of forensic toxicology as a scientific discipline. In 1814, Mathieiv J. B. Orfila (1787 to 1853), widely considered the "father of toxicology," published *Traité des Poisons*, the first systematic approach to the study of the chemical and physiological nature of poisons (Gettler, 1977). Orfila's role as an expert witness in many famous murder trials, particularly his application of the Marsh test for arsenic in the trial of the poisoner Marie Lafarge, aroused both popular and scholarly interest in the new science. As dean of the medical faculty at the University of Paris, Orfila trained numerous students in forensic toxicology.

The first successful isolation of an alkaloidal poison was performed in 1850 by Jean Servias Stas, a Belgian chemist, using a solution of acetic acid in warm ethanol to extract nicotine from the tissues of the murdered Gustave Fougnie. As modified by the German chemist Fredrick Otto, the Stas–Otto method was quickly applied to the isolation of numerous alkaloidal poisons, including colchicine, coniine, morphine, narcotine, and strychnine. In the latter half of the 19th century, European toxicologists were in the forefront of the development and application of forensic sciences, providing valuable evidence of poisoning. A number of these trials became "causes célèbres" and the testimony of forensic toxicologists captured the imagination of the public and increased awareness of the development and application of toxicology. It was thought that murderers could no longer poison with impunity.

In the United States, Rudolph A. Witthaus, professor of chemistry at Cornell University Medical School, made many contributions to toxicology and called attention to the new science by performing analyses for the city of New York in several famous morphine poisoning cases, including the murder of Helen Potts by Carlyle Harris and that of Annie Sutherland by Robert W. Buchanan. In 1911, Witthaus and Tracy C. Becker edited a four-volume work on medical jurisprudence, forensic medicine, and toxicology—the first standard forensic textbook published in the United States. In 1918, the city of New York established a medical examiner's system, and the appointment of Alexander O. Gettler as toxicologist marked the beginning of modern forensic toxicology in this country. Although Gettler made numerous contributions to the science, perhaps his greatest was the training and direction he gave to future leaders in forensic toxicology. Many of his associates went on to direct laboratories in medical examiner and coroner systems in major urban centers throughout the country.

In 1949, the American Academy of Forensic Sciences (AAFS) was established to support and further the practice of legal (forensic) medicine in the United States. The members of the Toxicology Section represented the vast majority of forensic toxicologists working in medical examiners' and coroners' offices, as well as numerous referral laboratories. Several other international, national, and local forensic science organizations, such as the Society of Forensic Toxicologists and the California Association of Toxicologists, offer a forum for the exchange of scientific data pertaining to analytical techniques and case reports involving new or infrequently used drugs and poisons. The International Association of Forensic Toxicologists (TIAFT) founded in 1963 with members from all regions of the world facilitates worldwide collaboration in resolving the technical problems confronting toxicology.

In 1975, the American Board of Forensic Toxicology (ABFT) was formed to examine and certify forensic toxicologists. One of the stated objectives of the board is "to make available to the judicial system, and other publics, a practical and equitable system for readily identifying those persons professing to be specialists in forensic toxicology who possess the requisite qualifications and competence." Those certified as Fellows of the Board must have a doctor of philosophy or science degree, have at least 3 years of full-time professional experience, and pass a written examination. Diplomates of the Board must have a bachelor's or master's degree, 3 years of full-time professional experience, and must pass a written examination.

In 1998, the ABFT began an accreditation program for forensic toxicology laboratories. ABFT-accredited laboratories must conform to standards of having qualified, experienced personnel and forensically sound procedures for the handling of evidence, analysis of specimens, and reporting of results. Laboratories must pass biannual on-site inspections, which include a review of laboratory procedures and casework.

TOXICOLOGICAL INVESTIGATION OF A POISON DEATH

The toxicological investigation of a poison death may be divided into three steps: (1) obtaining the case history and suitable specimens, (2) the toxicological analyses, and (3) the interpretation of the analytical findings.

Case History and Specimens

Today, thousands of compounds are readily available that are lethal if ingested, injected, or inhaled. Usually, a limited amount of specimen is available on which to perform analyses; therefore, it is imperative that, before the analyses are initiated, as much

information as possible concerning the facts of the case be collected. The age, sex, weight, medical history, and occupation of the decedent as well as any treatment administered before death, the gross autopsy findings, the drugs available to the decedent, and the interval between the onset of symptoms and death should be noted. In a typical year, a postmortem toxicology laboratory will perform analyses for such diverse poisons as over-the-counter medications (e.g., analgesics and antihistamines), prescription drugs (e.g., benzodiazepines and opioids), drugs of abuse (e.g., cocaine, marijuana, and methamphetamine), and gases (e.g., inhalants and carbon monoxide). Obviously, a thorough investigation of the death scene including a tentative identification of the administered poison is helpful prior to beginning the analysis (Ernst et al., 1982).

The pathologist at autopsy usually performs the collection of postmortem specimens for analysis. Specimens of many different body fluids and organs are necessary, as drugs and poisons display varying affinities for body tissues (Fig. 32-2). Therefore, detection of a poison is more likely in a tissue in which it accumulates. A large quantity of each specimen is needed for thorough toxicological analysis because a procedure that extracts and identifies one compound or class of compounds may be ineffective in extracting and identifying others (Table 32-2). Autolytic and putrefactive changes, however, may reduce specimen quality and therefore alter the selection and utility of individual specimens on a case-by-case basis. Further improvements in our knowledge regarding degradation mechanisms, as well as specimen-handling protocols to increase storage stability, may enable the forensic toxicologist to circumvent possible analytical and interpretive difficulties (Dinis-Oliveira et al., 2010).

When collecting the specimens, the pathologist labels each container with the date and time of autopsy, the name of the decedent, the identity of the sample, an appropriate case identification number, and his or her signature or initials. It is paramount that the handling of all specimens be authenticated and documented. A form developed at the collection site that identifies each specimen is submitted to the laboratory with the specimens. The form is signed and dated by the pathologist, and subsequently by any individual handling, transferring, or transporting the specimens. In legal terms, this form constitutes a "chain-of-custody" of specimens documenting all transfers. The chain-of-custody enables a toxicologist to introduce his or her results into legal proceedings, having established that the specimens analyzed were obtained from the decedent.

Fluids and tissues should be collected before embalming, as this process will dilute or chemically alter the poisons present, rendering their detection difficult or impossible. Conversely, methyl or ethyl alcohol may be a constituent of embalming fluid, thereby affecting interpretation of the analytical findings.

Although forensic toxicology laboratories typically receive blood, urine, liver tissue, and/or stomach contents for identification of xenobiotics, they have been increasingly called upon to meet the analytical challenges of many alternative types of samples (Skopp, 2004; Flanagan et al., 2005; Kronstrand and Druid, 2006; Gallardo and Queiroz, 2008). Nontraditional matrices, such as bone marrow, hair, and nails, among others, may be submitted to the laboratory. For example, on occasion, toxicological analysis is requested for cases of burned, exhumed, putrefied, and skeletal remains. In such instances, it is necessary to analyze unusual specimens such as bone marrow, hair, nails, skeletal muscle, and even insects (Inoue and Seta, 1992). Numerous drugs have been successfully identified in bone marrow and bone washings from skeletal remains even after decomposition and burial (Benko, 1985; Drummer, 2010; Cartiser et al., 2011). Similarly, the vitreous humor of the eye is isolated and sequestered from putrefaction, charring, and trauma; thus, it is a useful specimen for the detection of most drugs, anions, and even volatile poisons such as alcohols, ketones, and glycols (Coe, 1993; Bévalot et al., 2011). Hair analysis is a rapidly growing technique in forensic toxicology and has been used to measure individual exposure to heavy metals, such as arsenic, mercury, and lead, as well as many drugs of abuse and other pharmaceuticals, pesticides, and plastics (Hambidge, 1973; Yamaguichi et al., 1975; McKenzie, 1978; Baumgartner et al., 1981; Puschel et al., 1983; Suzuki et al., 1984; Marigo et al., 1986; Martz, 1988; Harkey and Henderson, 1989; Schroeder and Nason, 1989; Strang et al., 1990; Shen et al., 2002; Boumba et al., 2006). Analysis of hair for selected drugs has been utilized as an adjunct specimen in forensic settings for postmortem examinations for many years (Baumgartner et al., 1979; Couper et al., 1995; Gaillard and Pepin, 1997; Pragst et al., 1997; Rollins et al., 1997; Yegles et al., 1997; Muller et al., 2000; Villain et al., 2005; Pragst and Balikova, 2006; Kintz, 2010; Barroso et al., 2011). Nails, another keratinized matrix, have also been used to determine exposure to selected xenobiotics in both antemortem and postmortem cases (Palmeri et al., 2000; Garside, 2010). Limited data are available to support a direct

correlation between quantitative hair and nail values and drug doses in forensic cases; however, qualitative results have been accepted as indicators of previous drug or xenobiotic exposure.

Finally, in severely decomposed bodies, the absence of blood and/or the scarcity of solid tissues suitable for analysis have led to the collection and testing of maggots (fly larvae) feeding on the body (Pounder, 1991). The fundamental premise underlying maggot analysis is that if drugs or intoxicants are detected, they could only have originated from the decedent's tissues on which the larvae were feeding. Surprisingly, analysis of maggots is rather straightforward, requiring no special methodology beyond that routinely applied in toxicology laboratories. Case reports have documented the detection of numerous drugs and intoxicants in maggots collected from decomposed bodies. The compounds detected include barbiturates, benzodiazepines, phenothiazines, morphine, and malathion. Controlled studies in which maggots were allowed to feed on tissues to which drugs had been added have demonstrated the accumulation of propoxyphene, amitriptyline and nordiazepam, among others, in the larvae (Goff et al., 1993; Gagliano-Candela and Aventaggiato, 2001; Pien et al., 2004).

Toxicological Analysis

Before the analysis begins, several factors must be considered, including the amount of specimen available, the nature of the poison sought, and the possible biotransformation of the poison. In cases involving oral administration of the poison, the gastrointestinal (GI) contents are analyzed first because large amounts of residual unabsorbed poison may be present. The urine may be analyzed next, as the kidney is the major organ of excretion for most poisons and high concentrations of toxicants and/or their metabolites often are present in urine. After absorption from the GI tract, drugs or poisons are carried to the liver before entering the general systemic circulation; therefore, the first analysis of an internal organ is conducted on the liver. If a specific poison is suspected to have caused or contributed to a death, the toxicologist may first analyze the tissues and fluids in which the poison concentrates.

A thorough knowledge of drug biotransformation is often essential before an analysis is performed. The parent compound and any major pharmacologically active metabolites should be isolated and identified. In some instances, the metabolites provide the only evidence that a drug or poison has been administered. Many screening tests, such as immunoassays, are specifically designed to detect not the parent drug but its major urinary metabolite. An example of the relationship of pharmacokinetic and analytical factors is provided by cocaine. The major metabolites of cocaine biotransformation are benzoylecgonine and ecgonine methyl ester (Fig. 32-3). The co-ingestion of alcohol with cocaine results in the hepatic transesterification of cocaine to form cocaethylene (Hime et al., 1991), a psychoactive metabolite. The disposition of these compounds in various body fluids and tissues (including hair) is shown in Fig. 32-4. Thus,

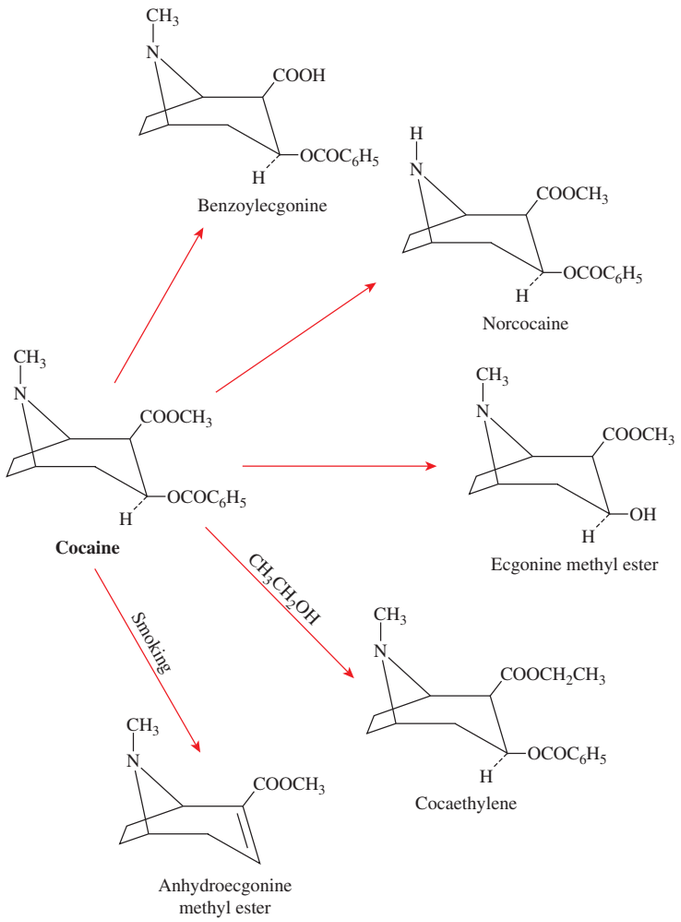

Figure 32-3. *Biotransformation and pyrolysis products of cocaine.*

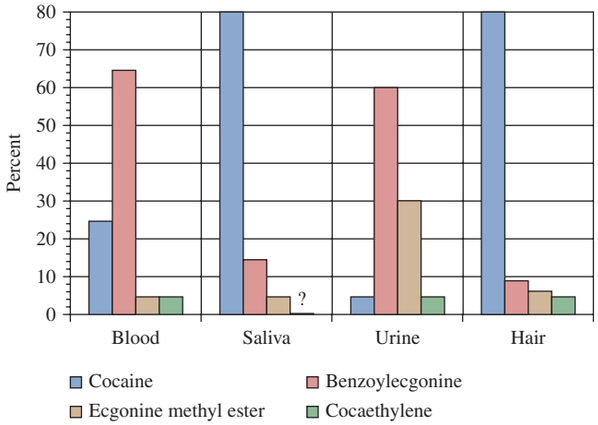

Figure 32-4. *Disposition of cocaine and cocaine metabolites in human fluids and hair.* (Data redrawn from Spiehler [1994].)

the initial testing of urine to determine cocaine use is performed with immunoassays specifically designed to detect the presence of benzoylecgonine, the major urinary metabolite. In contrast, if oral fluid (saliva) or hair is tested, parent cocaine, as well as metabolites, is also sought. To determine a profile of each analyte present in a specimen, chromatographic procedures such as gas chromatography (GC) and liquid chromatography (LC) coupled with mass spectrometry (MS) or tandem MS are commonly used, which facilitates the simultaneous separation and quantification of each compound.

Besides GC- and LC-MS targeted analysis, clinical and forensic toxicologists increasingly utilize high-resolution MS technologies including time-of-flight (TOF) and Orbitrap mass analyzers. This analytical advance offers retrospective data interrogation and versatile screening methods where new analytes can be rapidly included in the test panel (Wu et al., 2012; Kronstrand et al., 2014). The more recent generation of MS technologies interfaces quadrupole mass analyzer with TOF allowing higher resolution and greater mass accuracy for simultaneous screening and quantitative analyses of over a hundred drugs and metabolites (Bidny et al., 2017). Such analytical development is imperative to address the growing complexity and transience of the recreational drug market as the popularity of synthetic psychoactive substances known as designer drugs or novel/new psychoactive substances (NPS) has exponentially grown in the past decade (Pasin et al., 2017).

The analysis may be complicated by the normal chemical changes that occur during the decomposition of a cadaver. The autopsy and toxicological analysis should be started as soon after death as possible. The natural enzymatic and nonenzymatic processes of decomposition and microbial metabolism may destroy a poison that was present at death or produce substances or compounds with chemical and physical properties similar to those of commonly encountered poisons. As early as the 1870s, the so-called cadaveric alkaloids isolated from the organs of putrefied bodies were known to produce color test reactions similar to those produced by morphine and other drugs. These cadaveric alkaloids resulted from the bacterial decarboxylation of the amino acids ornithine and lysine, producing putrescine and cadaverine, respectively (Evans, 1963). Similarly, during decomposition, phenylalanine is converted to phenylethylamine, which has chemical and physical properties very similar to those of amphetamine. The hydrolysis, oxidation, or reduction of proteins, nucleic acids, and lipids may generate numerous compounds, such as hydroxylated aliphatic and aromatic carboxylic acids, pyridine and piperidine derivatives, and aromatic heterocyclics such as tryptamine and norharmane (Kaempe, 1969). All these substances may interfere with the isolation, identification, and quantitation of the toxicants being sought. The concentration of cyanide and ethyl alcohol and the carbon monoxide saturation of the blood may be decreased or increased, depending on the degree of putrefaction and microbial activity. However, many poisons—such as arsenic, barbiturates, mercury, and strychnine—are extremely stable and may be detectable many years after death.

Before analysis, the purity of all chemicals used in laboratory procedures should be established. The purity of the primary reference material used to prepare calibrators and controls should be verified, and the salt form or degree of hydration should be determined (Blanke, 1989). All reagents and solvents should be of the highest grade possible and should be free of contaminants that may interfere with or distort analytical findings. For example, the chloroform contaminants phosgene and ethyl chloroformate may react with primary or secondary amine drugs to form carbamyl chloride and ethyl carbamate derivatives (Cone et al., 1982). Specimen containers, lids, and stoppers should be free of contaminants such as plasticizers, which often interfere with chromatographic or GC/LC-MS determinations. Care should be exercised to ensure a clean laboratory environment. This is of particular concern in the analysis of metals, as aluminum, arsenic, lead, and mercury are ubiquitous environmental and reagent contaminants.

Forensic toxicology laboratories analyze specimens by using a variety of analytical procedures. Initially, nonspecific tests designed to determine the presence or absence of a class or group of analytes may be performed directly on the specimens. Examples of tests used to rapidly screen urine are the FPN (ferric chloride, perchloric, and nitric acid) color test for phenothiazine drugs and immunoassays for the detection of amphetamines, benzodiazepines, and opiate derivatives, among others. Positive results obtained with these tests must be confirmed by a second analytical procedure that identifies the particular drug. The detection limit of the confirmatory test should be lower than that of the initial nonspecific test. Some analytical procedures identify specific compounds. Even in such instances, a second test should be performed to identify and confirm the presence of the analyte. The second test should be based on a chemical or physical principle different from that of the first test. Such additional testing is performed to establish an unequivocal identification of the drugs or poisons present. Whenever possible, the most specific test for the compound of interest should be performed. Today, GC-MS and LC-MS are the most widely applied methodology in toxicology and are generally accepted as unequivocal identification for all drugs. Analyte identification is typically based on the retention time in the chromatographic system coupled with the characteristic ion fragmentation spectrum in the mass spectrometer. The analyte mass spectrum is the pattern of mass-to-charge ion fragments and their relative abundance.

Analytical methods must be of sufficient rigor to provide accurate and reliable qualitative and quantitative data. Numerous approaches for the use of quality control have been suggested, and professional organizations have developed recommendations for the implementation of quality control in forensic laboratories (Goldberger et al., 1997; Ferrara et al., 1998; Scientific Working Group for Forensic Toxicology, 2013). The limit of detection, the lowest concentration of analyte reliably identified by the assay, and the specificity of all qualitative methods should be well documented. The laboratory must demonstrate that the assay response of blank or negative calibrators (controls) does not overlap with the response of the lowest-positive calibrator. In certain instances, qualitative identification of a poison or drug is sufficient to resolve forensic

toxicology issues. However, most cases require reliable estimates of poison concentrations for forensic interpretation. For quantitative analysis, the accuracy, precision, linearity, and specificity of the procedure must also be established. Linearity should be determined by using multiple drug-fortified calibrators whose concentrations bracket the anticipated concentrations in the biological specimen. Precision, which statistically demonstrates the variance in the value obtained, is determined by replicate analyses of a specimen of a known concentration. Additional assay parameters, such as analyte stability and recovery from the biological matrix, for example, can also be determined. For a variety of reasons, a quantitative result occasionally will deviate spuriously from the true value. Therefore, replicate quantitative determinations are highly recommended when sufficient specimen volume is available (Blanke, 1987).

When unusual samples such as bone marrow, fingernails, hair, and maggots are analyzed, the extraction efficiency of a procedure may vary greatly, depending on the complexity of the matrix. Therefore, all calibrators and controls should be prepared in the same matrix type as the specimens and analyzed concurrently with the specimens. Often the matrix is "unique" or impossible to match, such as decomposed or embalmed tissue. In these instances, the method of "standard additions" may be used. Known amounts of the analyte of interest are added to specimen aliquots and these are analyzed. The concentration of poison in the test specimen is determined by comparing the proportional response of the "poison fortified" specimens to that of the test specimens.

Interpretation of Analytical Results

Once the analysis of the specimens is complete, the toxicologist must interpret his or her findings with regard to the physiological or behavioral effects of the toxicants on the decedent at the concentrations found. Specific questions may be answered, such as the route of administration, the dose administered, and whether the concentration of the toxicant present was sufficient to cause death or alter the decedent's actions enough to cause his or her death. Assessing the physiological or behavioral meanings of analytical results is often the most challenging aspect confronted by the forensic toxicologist.

In determining the route of administration, the toxicologist notes the results of the analysis of the various specimens. As a general rule, the highest concentrations of a poison are found at the site of administration. Therefore, the presence of large amounts of drugs and/or poisons in the GI tract and liver indicates oral ingestion, while higher concentrations in the lungs than in other visceral organs can indicate inhalation or intravenous injection. The ratio or relative distribution of drugs in different tissues may also differentiate oral from parenteral administration (Fig. 32-5). Drugs may also be detected in the tissue surrounding an injection site following intramuscular or intravenous injection. Smoking is a popular route of administration for abusers of controlled substances (illicit) such as cocaine, heroin, marijuana, and phencyclidine. Pyrolysis of these drugs leads to the inhalation not only of the parent drug, but also of characteristic breakdown products of combustion. For example, a major pyrolysis product of "crack" cocaine smoking is anhydroecgonine methyl ester (Martin et al., 1989) (Fig. 32-3). Thus, identification of relatively high concentrations of this compound along with cocaine or cocaine metabolites in urine or other body fluids or tissues may indicate smoking as the route of cocaine administration (Jacob et al., 1990).

The presence of a toxic material in the GI tract, regardless of the quantity, does not provide sufficient evidence to establish that agent as the cause of death. It is necessary to demonstrate that

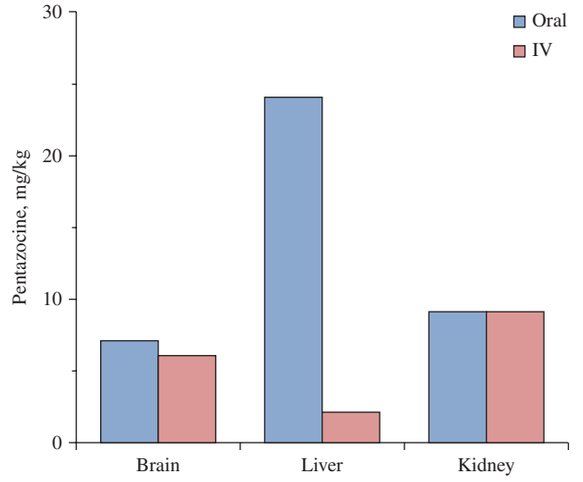

Figure 32-5. *Comparison of pentazocine distribution in fatal poisonings due to intravenous injection and oral administration.* (Data from Baselt [1982]; Poklis and MacKell [1982].)

absorption of the toxicant has occurred and that it has been transported by the general circulation to the target organ in order to exert its lethal effect. This is established by blood and tissue analyses. An exception to the rule is provided by strong, corrosive chemicals such as sulfuric acid, lye, and phenol, which exert their deleterious effects by directly digesting tissue, causing hemorrhage and shock. The results of urinalysis are often of little benefit in determining the physiological effects of a toxic agent. Urine results establish only that the poison was present in the body at some time before death. Correlation of urine values with physiological effects is poor because of various factors that influence the rate of excretion of specific compounds and the urine volume.

The physiological effects of most drugs and poisons are generally correlated with their concentrations in blood or blood fractions such as plasma and serum. Indeed, in living persons, this association is the basis of therapeutic drug monitoring. However, postmortem blood has been described as a fluid resembling blood that is obtained from the vasculature after death. Therefore, interpretation of postmortem blood results requires careful consideration of the case history, the site of collection, and postmortem changes. The survival time between the administration of a poison and death may be sufficiently long to permit biotransformation and excretion of the agent. Blood values may appear to be nontoxic or consistent with therapeutic administration. Death from hepatic failure after an acetaminophen overdose usually occurs at least 3 to 4 days after ingestion. Postmortem acetaminophen concentrations in blood may be consistent with the ingestion of therapeutic doses. Therefore, fatal acetaminophen overdose is determined by case history, central lobular necrosis of the liver, and, if available, analysis of serum specimens collected from the decedent when he or she was admitted to the emergency department (Price et al., 1991). Furthermore, emergency medical treatment—such as the administration of fluids, plasma extenders, bicarbonate, diuretics, and blood transfusions—may dilute, remove, or enhance the elimination of toxic agents. Similarly, prolonged survival on a mechanical respirator, hemodialysis, or hemoperfusion may substantially reduce initially lethal blood concentrations of poisons.

For a long time, it was generally assumed that postmortem blood drug concentrations were more or less uniform throughout the

body. However, in the 1970s, several investigators noted that postmortem concentrations of digoxin in heart blood greatly exceeded those in simultaneously collected femoral blood. They also observed that postmortem blood concentrations, particularly in heart blood, exceeded the expected values at the time of death (Vorpahl and Coe, 1978; Aderjan et al., 1979). This postmortem increase in blood digoxin concentrations was apparently due to release of the drug from tissue stores, particularly the myocardium. Subsequently, other researchers demonstrated that for many drugs, blood concentrations in the same body vary greatly depending on the site from which the specimen is collected—subclavian vein, thoracic aorta, inferior vena cava, femoral vein, and so forth. For example, in a case of fatal multiple drug ingestion, analysis of postmortem blood collected from 10 different sites demonstrated imipramine concentrations that differed by as much as 760% (2.1 to 16.0 mg/L) (Jones and Pounder, 1987). In an extensive investigation, Prouty and Anderson (1990) demonstrated that postmortem blood drug concentrations were not only site-dependent but also increased greatly over the interval between death and specimen collection, particularly in heart blood. This increase over the postmortem interval was most pronounced for basic drugs with large apparent volumes of distribution, such as tricyclic antidepressants.

In an overt drug overdose, postmortem blood concentrations are elevated sufficiently to render an unmistakable interpretation of fatal intoxication. However, in many cases, the postmortem redistribution of drugs may significantly affect the interpretation of analytical findings. For drugs whose volume of distribution, plasma half-life, and renal clearance vary widely from person to person or that undergo postmortem redistribution, tissue concentrations readily distinguish therapeutic administration from drug overdose (Apple, 1989). Therefore, to provide expert opinions with a sound scientific foundation in regard to the role of a drug in the death of an individual, it is recommended that, in addition to heart blood, a peripheral blood specimen and tissues be analyzed.

The analysis of tissue specimens is important for the estimation of a "minimal administered dose" or body burden of a drug or poison. In order to calculate a minimum body burden, it is necessary to analyze as many different body tissues and fluids as possible to determine the concentrations of the drug present. The concentration of drug in each separate specimen is then multiplied by the total weight or volume of that particular tissue or fluid. In this manner, the total amount of drug in each different tissue or fluid is determined. The amounts of drug in each separate tissue and fluid are then added together to give the total body burden or minimal administered dose. This simple approach has often proven extremely effective in resolving legal medical issues. For example, lidocaine is commonly administered in 50- to 100-mg bolus injections as an antiarrhythmic agent for ventricular arrhythmia during resuscitation efforts. Because of poor circulation and tissue perfusion during arrhythmias, lidocaine is not well distributed in the body of the victim of a fatal heart attack. Postmortem bloods often exceed 50 mg/L in such cases, whereas values for effective antiarrhythmic prophylaxis do not exceed 5 mg/L. Therefore, a blood lidocaine value of 50 mg/L may be an artifact of resuscitation efforts or might represent a fatal overdose. Tissue distribution studies have resolved this issue in both accidental and homicidal poisoning with lidocaine (Poklis et al., 1984).

Postmortem toxicology results are often used to corroborate investigative findings. Improved methods for determining drug exposure, with respect to longer timeframes, are advantageous because drug concentrations in plasma, urine, and liver often reflect only the dosage taken within (at most) the last several days prior to sampling. Compared to traditional biological matrices, keratinized tissues such as hair and nails provide a longer window of detection for drugs and other compounds due to their slow growth and possible permanent retention of drugs. The presence of certain xenobiotics and their metabolites has been demonstrated in human hair or nails at times when plasma and urine drug concentrations are not measurable (Rollins et al., 1997; Garside, 2010), which can provide evidence of exposure to these agents weeks, months, or even years prior to death. It has been suggested that for some xenobiotics, hair also serves to characterize the drug exposure over time. For example, the analysis of sequential sections of hair provides a reliable correlation with the pattern of arsenic exposure (Smith, 1964). Significant increases in the arsenic content of the root and the first 5 mm of the hair occur within hours after the ingestion of arsenic. The germinal cells are in relatively close equilibrium with circulating arsenic; thus, as arsenic concentrations in blood rise or fall, so does arsenic deposition in growing hair. Normal arsenic content in hair varies with nutritional, environmental, and physiological factors; however, the maximum upper limit of normal deposition with a 99% confidence limit in persons not exposed to arsenic is 5 mg/kg (Shapiro, 1967). Hair grows at a rate of approximately 1.06 cm per month (LeBeau et al., 2011). Therefore, analysis of 1.0-cm segments provides a monthly pattern of exposure (Fig. 32-6). Such analyses can be performed in cases of homicidal poisoning to demonstrate that increases in arsenic deposition in the victim's hair correlate with times when a poisoner had an opportunity to administer the poison. Continuously elevated hair arsenic values indicate chronic rather than acute poisoning as the cause of death. A similar approach using segmental analysis of hair has been used to determine patterns of exposure for various drugs and their metabolites; however, care must be taken in order to account for the potential effects of haircuts, chemical treatments, and other environmental insults that may have occurred to the hair during the timeframe of interest.

An extension of forensic toxicology is the analysis of impurities of illicit drug synthesis in biological specimens. Many drugs of abuse, particularly methamphetamine, are illicitly manufactured

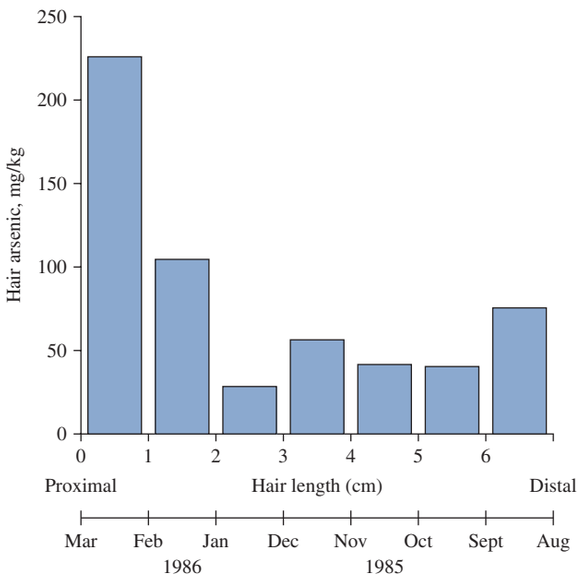

Figure 32-6. *Results of neutron activation analysis for arsenic in sequential sections of hair, demonstrating chronic arsenic poisoning.* Increased exposure in the first two sections is consistent with fatal events. Lower values in section three are consistent with 2 weeks of hospitalization. (Data from Poklis and Saady [1990].)

in clandestine laboratories. There are several popular methods of methamphetamine synthesis; when these are applied in clandestine laboratories, side reactions or incomplete conversion of the reactants yield an impure mixture of methamphetamine and synthetic impurities. These impurities can be characteristic of a particular synthetic method, and their detection in biological specimens can indicate the use of an illicitly produced drug that is not a legal pharmaceutical product, suggest the synthetic method that was used to produce the drug, point to a possible common source of illicit production, and provide a link between manufacturers, dealers, and users. An example of impurity analysis was the detection of metabolites of α-benzyl-*N*-methylphenethylamine (BNMPA) in the urine of abusers of methamphetamine (Moore et al., 1996b) and in a case of fatal drug overdose involving methamphetamine (Moore et al., 1996a). BNMPA is an impurity arising from the synthesis of methamphetamine via the Leukart reaction using phenyl-2-propanone (P2P) synthesized from phenylacetic acid. Clandestine laboratories often must synthesize the P2P starting material, as its sale and distribution is regulated by the U.S. Drug Enforcement Administration.

As discussed above, a wide range of tissues are available for the purpose of identifying xenobiotics in postmortem specimens. In contrast, for many years, traditional specimens used for the detection and quantification of substances in antemortem biological specimens have been limited to whole blood, plasma, serum, and urine, largely due to their ease of collection and accessibility in the living. More recently, the advent of improved analytical techniques with greater sensitivity and selectivity, including GC-MS/MS and LC-MS/MS, have expanded the array of biological specimens in which substances can be detected. These specimens include oral fluid (saliva), sweat, meconium, amniotic fluid, breast milk, and semen among others. In oral fluid, for example, the pharmacokinetics of many drugs and metabolites is closely aligned to that of blood pharmacokinetics, and thus can serve as an alternative matrix for illicit and therapeutic drug detection (Bosker and Huestis, 2009; Spiehler and Cooper, 2010), as well as detection of exposure to environmental toxicants and pesticides (Lanaro et al., 2011; Yang et al., 2011).

CRIMINAL POISONING OF THE LIVING

Over the past few decades, forensic toxicologists have become more involved in the analysis of specimens obtained from living victims of criminal poisonings. Generally, this increase in testing is a result of two types of cases: (1) administration of drugs to incapacitate victims of kidnapping, robbery, or sexual assault and (2) poisoning as a form of child abuse.

For centuries, those severely intoxicated from alcohol often became victims of kidnapping, robbery, or sexual assault. The kidnapping of drunks in seaports was a common way of obtaining sailors for long commercial voyages such as those involved in whaling. Late in the 19th century, the mixing of the powerful hypnotic chloral hydrate with alcohol produced the legendary "Mickey Finn." While alcohol is still often a primary factor in cases of alleged sexual assault, common drugs of abuse or other psychoactive drugs are often involved (Table 32-3). Of particular concern are the many potent inductive agents medically administered prior to general anesthesia. Many of these drugs, such as benzodiazepines and phenothiazines, are available today through illicit sources or legal purchase in foreign countries. When administered surreptitiously, they cause sedation and incapacitate the victim while also producing amnesia in the victim as to the events while drugged, without causing severe central nervous system depression. These cases often present a difficult analytical challenge to the toxicologist. Usually, the victim does not bring forth an allegation of assault until 24 hours to several days after the attack. Thus, the intoxicating drug may have been largely eliminated or extensively metabolized such that extremely low concentrations of drug or metabolites are present in the victim's blood, urine, and/or hair specimens. Sophisticated, highly sensitive analytical methods such as GC-MS or LC-MS may be required to accurately identify drugs in such specimens. To provide guidance in the choice of analytical approaches to such cases, recommendations for the toxicological investigation of drug-facilitated crimes including sexual assaults have been formulated (LeBeau et al., 1999; Society of Forensic Toxicologists).

Poisoning as a form of child abuse involves the deliberate administration of toxic or injurious substances to a child, usually by a parent or other caregiver. The victims of such poisonings range in age from a few months to the teens. Common agents used to intentionally poison children have included syrup of ipecac, table salt, laxatives, diuretics, antidepressants, sedative-hypnotics, and narcotics (Yin, 2010; American Association of Poison Control Centers, 2011; Oral et al., 2011). The motivation for such heinous behavior is in the province of psychiatry, not toxicology. However, toxicologists must have some understanding of the nature of these poisonings to aid in the investigation of such cases. In some instances, it is a form of child battering committed by persons with low tolerance to the child's upsetting behaviors. The poison may be given to an infant to stop its crying or be force-fed to older children as a form of punishment. Such behavior is characteristic of persons with a cultural background where violence toward children is common or who have severe personality disorders or other mental illnesses. "Munchausen syndrome by proxy" is another form of child poisoning (Murray, 1997). The term *Munchausen syndrome* (MS) is used to describe patients who seek admission to hospitals with apparent illness along with plausible, dramatic, albeit fictitious medical histories. Such people seek medical treatment solely to assume the role of a patient and receive the attention derived from this deception. "MS by proxy" refers to the situation in which an individual, usually a parent, presents not himself or herself but a child with

Table 32-3

Distribution of Drugs of Abuse Encountered Urine Specimens in 1179 Cases of Alleged Sexual Assault*

RANK	DRUG/DRUG GROUP	INCIDENCE
1	No drugs found	468
2	Ethanol	451
3	Cannabinoids	218
4	Benzoylecgonine (cocaine metabolite)	97
5	Benzodiazepines	97
6	Amphetamines	51
7	Gamma-hydroxybutyrate (GHB)	48
8	Opiates	25
9	Propoxyphene	17
10	Barbiturates	12

**Thirty-five percent of the drug-positive specimens were positive for more than one drug.*

SOURCE: Data from ElSohly and Salamone (1999).

a fictitious illness often induced by physical or chemical means. The purpose of the poisoning is not to kill the child but to induce signs and symptoms of illness that will assure medical attention. Thereby, the parent as caregiver gains the craved attention. Given a fictitious case history and the obvious illness of the child, these cases are almost always and understandably misdiagnosed. Often, the child may be chronically poisoned at home and in the hospital for as long as a year before suspicion leads to the collection of specimens for extensive toxicological testing. Although the parent may not have intended such an outcome, some children have died from fatal poisoning in these situations. As in the case of sexual assault, sophisticated MS testing methods may be required to detect such chemicals as emetine and cephaeline, the emetic alkaloids in syrup of ipecac. Testing in these cases is best performed in a laboratory with forensic experience, as positive drug findings will usually result in some form of legal proceeding.

FORENSIC DRUG TESTING

Concerns regarding the potentially adverse consequences of substance abuse for the individual, the workplace, and society have led to widespread urine analysis for controlled or illicit drugs (Gust and Walsh, 1989). Currently, such testing is conducted routinely by the military services, regulated transportation and nuclear industries, many federal and state agencies, public utilities, federal and state criminal justice systems, and numerous private businesses and industries. Significant ethical and legal ramifications are associated with such testing. Those having positive test results may not receive employment, be dismissed from a job, be court-martialed, or suffer a damaged reputation.

To assure the integrity of workplace urine testing, two certification programs currently accredit forensic urine-testing laboratories. Laboratories conducting testing of federal employees are required to be certified under the Department of Health and Human Services (HHS) Mandatory Guidelines for Workplace Drug Testing as published in the April 11, 1988, *Federal Register*, which has been periodically revised; the latest revision was published in the January 23, 2017, *Federal Register* where HHS allowed collection of an alternative specimen such as oral fluid (Department of Health and Human Services, 1988, 2017). The College of American Pathologists (CAP) also conducts a certification program for urine drug testing laboratories. The federal program regulates the process from specimen collection through testing to the reporting of results, whereas the CAP program allows flexibility in the construction of programs servicing a broad range of clients. Both programs involve proficiency testing and periodic on-site inspection of laboratories.

Forensic drug testing differs from other areas of forensic toxicology in which urine or an alternative specimen is the only specimen analyzed and testing is performed for a limited number of drugs and metabolites. While urine remains as the most prevalent biological matrix for forensic drug testing, the popularity of oral fluid as an alternative matrix is increasing because the collection is more convenient and less invasive (Tsanaclis et al., 2012). Under the federal certification program, analyses are performed for a limited number of classes or drugs of abuse (Table 32-4). While HHS-certified laboratories may typically analyze hundreds to thousands of urine specimens daily, only a relatively small number of those specimens are positive for drugs. To handle this large workload, initial testing is performed by immunoassays on rapid, high-throughput chemistry analyzers. A confirmation analysis in HHS-certified laboratories is performed by GC-MS and LC-MS/MS.

Proper forensic drug testing is a challenge to good laboratory management. As with all forensic activities, every aspect of the laboratory operation must be thoroughly documented—specimen collection, chain of custody, quality control procedures, method validation, testing, qualifications of personnel, and the reporting of results. The laboratory facility must be constructed and operated to assure total security of specimens and documents. Confidentiality of all testing results is paramount; only specifically authorized persons should receive the results. The presence of a controlled or illicit drug in a single random urine specimen is generally accepted as proof of recent or past substance abuse. However, positive urine drug findings are only evidence that, at some time before the collection of the sample, the individual was administered the drug, self-administered it, or was exposed to it. Positive urine tests do not prove impairment from drug abuse or addiction.

Forensic drug test results are reported only as positive or negative for the drugs sought. Cutoff values are established for both

Table 32-4

Forensic Urine Drug Testing Analytes and Cutoff Concentrations

	CONCENTRATION (ng/mL)	
ANALYTE	INITIAL TEST	CONFIRMATORY TEST
Marijuana metabolites	50	
Δ-9-tetrahydrocannabinol-9-carboxylic acid	–	15
Cocaine metabolite	150	
Benzoylecgonine	–	100
Opiates	2000	
Morphine	–	2000
Codeine	–	2000

Hydrocodone	–	100
Hydromorphone	–	100
Oxycodone/oxymorphone	100	
Oxycodone	–	100
Oxymorphone	–	100
6-Acetylmorphine (heroin metabolite)	10	10
Phencyclidine	25	25
Amphetamines	500	
Amphetamine	–	250
Methamphetamine	–	250
MDMA/MDA	500	
MDMA	–	250
MDA	–	250

SOURCE: Department of Health and Human Services: Mandatory guidelines for federal workplace drug testing programs. Fed Reg. 53(69), 11983, April 11, 1988; revised: Fed Reg. 82(13), 7920, October 1, 2017. https://www.federalregister.gov/documents/2017/01/23/2017-00979/mandatory-guidelines-for-federal-workplace-drug-testing-programs.

the initial and confirmation assays (Table 32-4). The cutoff value is a concentration at or above which the assay is administratively considered positive. Below the cutoff value, the assay is reported to be negative for that drug or drug class. Obviously, drugs may be present below the cutoff concentration. However, the use of cutoff values allows uniformity in the drug testing and reporting of results. All test reports indicate the drug tested and its cutoff value. The testing laboratories must be thoroughly familiar with all regulatory and analytical issues related to urine testing and devise strategies to resolve uncertainties.

Many individuals who are subject to regulated urine testing have devised techniques to mask their drug use either by physiological means such as the ingestion of diuretics or by attempting to adulterate the specimen directly with bleach, vinegar, or other products that interfere with the initial immunoassay tests (Warren, 1989; George and Braithwaite, 1996; Ferslew et al., 2003; Paul, 2004; Burrows et al., 2005). Thus, specimens are routinely tested for adulteration by checking urinary pH, creatinine, and specific gravity, nitrates, chromates, and noting any unusual color or smell. A mini-industry has developed to sell various products that are alleged to "beat the drug test." These products contain chemicals that, when added to a urine specimen, interfere with either the initial or confirmatory drug test (Dasgupta, 2007; Jaffee et al., 2007; Larson et al., 2008). For example, several of these products contain glutaraldehyde, which will react with the nitrogen atoms of the antibody proteins of the immunoassay screening test, thereby cross-linking the antibodies and inactivating the assay. However, this disruption of the test is so complete that the immunoassay analyzer records almost no signal, thus indicating possible adulteration of the specimen. Another adulterant, for the marijuana metabolite urine test, contains sodium nitrite. In acidic urine, the nitrite salt is converted to nitrous acid that then converts the marijuana metabolites to nitroso derivatives, rendering them undetectable by routine GC-MS analysis (Lewis et al., 1999). Often, the pH of the urine is insufficiently acidic for complete nitroso conversion of the tetrahydrocannabinol (THC) metabolite, THC-carboxylic acid. Thus, the urine will screen positive by the initial immunoassay. When urine is acidified to extract the THC acid metabolite for MS confirmation testing, the metabolite is completely oxidized and undetectable. However, the deuterated THC–carboxylic acid added to the sample as the internal standard of the confirmation test is also completely destroyed. Failure to detect the internal standard readily alerts the analyst that an oxidant adulterant had been added to the urine. In such cases, a quantitative test for nitrite is performed. Nitrite may be present in urine from numerous internal and external sources such as foods, drugs, pathological conditions, and infection from nitrate-reducing microorganisms. However, none of these sources produces urinary nitrite concentrations that even begin to approach those obtained by the addition of adulterant amounts of potassium nitrite equal to 1000 mg/L (Urey et al., 1998). Most chemical adulterants can be detected in urine by specific colorimetric tests that can be readily adapted to high-volume auto-analyzers (Table 32-5). Thus, the laboratories now routinely test not only for drugs of abuse but also for a wide variety of chemical adulterants. In most instances, a positive test result for adulteration has a consequence similar to a positive drug test.

There may be valid reasons other than substance abuse for positive drug findings, such as therapeutic use of controlled substances, inadvertent intake of drugs via food, and passive inhalation. For example, the seed of *Papaver somniferum*, poppy seed, is a common ingredient in many pastries and breads. Depending on their botanical source, poppy seeds may contain significant amounts of morphine. Several studies have demonstrated that the ingestion of certain poppy-seed foods results in the urinary excretion of readily detectable concentrations of morphine (ElSohly and Jones, 1989). Morphine is a major urinary metabolite of heroin. Therefore, to readily differentiate heroin abuse from poppy-seed ingestion, analysis may be performed for 6-acetylmorphine, a unique heroin metabolite (Fehn and Megges, 1985).

Even over-the-counter medications may present potential problems for laboratories conducting urine drug testing. Methamphetamine may occur as a racemic mixture of D- and L-optical isomers. D-Methamphetamine, a Schedule II controlled substance, is a potent central nervous system stimulant subject to illicit drug abuse, while L-methamphetamine (L-desoxyephedrine) is an alpha-adrenergic stimulant available in over-the-counter Vicks® inhalers as a nasal decongestant. Cross-reactivity of L-desoxyephedrine with the initial immunoassay screening test may occur after excessive use of the Vicks inhaler (Poklis and Moore, 1995). Additionally, the most popular conformational GC-MS products for amphetamines are achiral. Therefore, if such analyses are performed, a "false-positive" result for D-methamphetamine may be reported. This dilemma is easily resolved if confirmation testing is done with a chiral GC-MS procedure, which can readily resolve the stereoisomers of methamphetamine (Fitzgerald et al., 1988).

HUMAN PERFORMANCE TESTING

Forensic toxicology activities also include the determination of the presence of ethanol and other drugs and chemicals in blood, breath, or other specimens and the evaluation of their role in modifying human performance and behavior. The most common application of human performance testing is to determine impairment while driving under the influence of ethanol (DUI) or drugs (DUID). Although operation of a motor vehicle is a common experience to most people, few appreciate the complexity of mental and physical functioning involved. A driver must simultaneously coordinate fine motor skills in tracking the road course and applying pressure to accelerator or brake—with visual attention immediately in front, to the horizon, and to the periphery of the vehicle—while continuously judging distance, speed, and appropriateness of response to signals, traffic, and unexpected events. The threshold blood alcohol concentration (BAC) for diminished driving performance of these complex functions in many individuals is as low as 0.04 g/dL, the equivalent of ingestion of two beers within an hour's time to

Table 32-5

Urine Adulterants Detected by Chemical Test

ADULTERANT	DETECTION METHOD
Acids, baking soda	pH
Bleach	Smell, color test
Detergents, diuretics, salt	Specific gravity
Diuretics	Creatinine, specific gravity
Glutaraldehyde	Color test, gas chromatography
Nitrite	Color test
Pyridinium chlorochromate	Color test, atomic absorption spectrophotometry (chromate), gas chromatography (pyridine)

an average size person. The statutory definition of DUI in all 50 states is a BAC of 0.08 g/dL; the state of Utah recently passed the law that lowers the legal threshold to 0.05 g/dL, which will take effect in December 2018 (Utah Department of Public Safety, n.d.). These concentrations are consistent with diminished performance of complex driving skills in the vast majority of individuals. Over the past half century, an enormous amount of data has been developed correlating blood ethanol concentrations with intellectual and physiological impairment, particularly of the skills associated with the proper operation of motor vehicles. Numerous studies have demonstrated a direct relationship between an increased BAC in drivers and an increased risk of involvement in vehicular accidents (Council on Scientific Affairs, 1986). For example, alcohol-impaired driving fatalities accounted for 28% of all motor vehicle traffic fatalities in the United States in 2016 (National Highway Traffic Safety Administration, 2017).

During the past decade, there has been growing concern about the deleterious effects of drugs other than ethanol on driving performance. Several studies have demonstrated a relatively high occurrence of drugs in impaired or fatally injured drivers (White et al., 1981; Mason and McBay, 1984; Van der Linden et al., 2013). These studies tend to report that the highest drug-use accident rates are associated with the use of such illicit or controlled drugs as cocaine, benzodiazepines, marijuana, and phencyclidine. However, most studies test for only a few drugs or drug classes, and the repeated reporting of the same drugs may be a function of limited testing. Before "driving under the influence of drugs" testing is as readily accepted by the courts as ethanol testing, many legal and scientific problems concerning drug concentrations and driving impairment must be resolved (Consensus Report, 1985). The ability of analytical methodology to routinely quantify minute concentrations of drug in blood must be established. Also, drug-induced driving impairment at specific blood concentrations in controlled tests and/or actual highway experience must be demonstrated.

COURTROOM TESTIMONY

The forensic toxicologist often is called upon to testify in legal proceedings. As a general rule of evidence, a witness may testify only to facts known to him or her. The witness may offer opinions solely on the basis of what he or she has observed (Moenssens et al., 1973). Such a witness is called a "lay witness." In contrast, the toxicologist is referred to as an "expert witness." A court recognizes a witness as an expert if that witness possesses knowledge or experience in a subject that is beyond the range of ordinary or common knowledge or observation. An expert witness may provide two types of testimony: objective testimony and "opinion." Objective testimony by a toxicologist usually involves a description of his or her analytical methods and findings. When a toxicologist testifies as to the interpretation of his or her analytical results or those of others, that toxicologist is offering an "opinion." Lay witnesses cannot offer such opinion testimony, as it exceeds their ordinary experience.

Before a court permits opinion testimony, the witness must be "qualified" as an expert in his or her particular field. In qualifying someone as an expert witness, the court considers the witness's education, on-the-job training, work experience, teaching or academic appointments, and professional memberships and publications as well as the acceptance of the witness as an expert by other courts. Qualification of a witness takes place in front of the jury members, who consider the expert's qualifications in determining how much weight to give to his or her opinions during their deliberations.

Whether a toxicologist appears in criminal or civil court, workers' compensation, or parole hearings, the procedure for testifying is the same: direct examination, cross-examination, and redirect examination. The attorney who has summoned the witness to testify conducts direct examination. Testimony is presented in a question-and-answer format. The witness is asked a series of questions that allow him or her to present all facts or opinions relevant to the successful presentation of the attorney's case. During direct examination, an expert witness has the opportunity to explain to the jury the scientific bases of his or her opinions. Regardless of which side has called the toxicologist to court, the toxicologist should testify with scientific objectivity. Bias toward his or her client and prejudgments should be avoided. An expert witness is called to provide informed assistance to the jury. The jury, not the expert witness, determines the guilt or innocence of the defendant.

After direct testimony, the opposing attorney questions the expert. During this cross-examination, the witness is challenged as to his or her findings and/or opinions. The toxicologist will be asked to defend his or her analytical methods, results, and opinions. The opposing attorney may imply that the expert's testimony is biased because of financial compensation, association with an agency involved in the litigation, or personal feelings regarding the case. The best way to prepare for such challenges before testimony is to anticipate the questions the opposing attorney may ask.

After cross-examination, the attorney who called the witness may ask additional questions to clarify any issues raised during cross-examination. This allows the expert to explain apparent discrepancies in his or her testimony raised by the opposing attorney. Often, an expert witness is asked to answer a special type of question, the "hypothetical question." A hypothetical question contains only facts that have been presented in evidence. The expert is then asked for his or her conclusion or opinion based solely on this hypothetical situation. This type of question serves as a means by which appropriate facts leading to the expert's opinion are identified. These questions are extremely long and convoluted. The witness should be sure he or she understands all the facts and implications in the question. Like all questions, this type should be answered as objectively as possible.

ROLE IN CLINICAL TOXICOLOGY

Analytical toxicology in a clinical setting plays a role very similar to its role in forensic toxicology. As an aid in the diagnosis and treatment of toxic incidents, as well as in monitoring the effectiveness of treatment regimens, it is useful to clearly identify the nature of the toxic exposure and measure the amount of the toxic substance that has been absorbed. Frequently, this information, together with the clinical state of the patient, permits a clinician to relate the signs and symptoms observed to the anticipated effects of the toxic agent. This may permit a clinical judgment as to whether the treatment must be vigorous and aggressive or whether simple observation and symptomatic treatment of the patient are sufficient.

A cardinal rule in the treatment of poisoning cases is to remove any unabsorbed material, limit the absorption of additional poison, and hasten its elimination. The clinical toxicology laboratory serves an additional purpose in this phase of the treatment by monitoring the amount of the chemical remaining in circulation or measuring what is excreted. In addition, the laboratory can provide the data needed to permit estimations of the total dosage or the effectiveness of treatment by changes in known pharmacokinetic parameters of the drug or other chemical ingested.

Although the instrumentation and the methodology used in a clinical toxicology laboratory are similar to those utilized by a forensic toxicologist, a major difference between these two applications is responsiveness. In emergency toxicology testing, results

must be communicated to the clinician within hours to be meaningful for therapy. A forensic toxicologist may carefully choose the best method for a particular test and conduct replicate procedures to assure maximum accuracy. A clinical laboratory cannot afford this luxury and may sacrifice accuracy for a rapid turnaround time. Additionally, because it is impossible to predict when toxicological emergencies will occur, a clinical laboratory must provide rapid testing 24 hours a day, every day of the year.

Primary examples of the usefulness of emergency toxicology testing are the rapid quantitative determination of acetaminophen, salicylate, alcohols, and glycol serum concentrations in instances of suspected overdose. Acetaminophen serum values related to the time after ingestion (see Chap. 33) not only indicate an overdose, but provide a prognosis for possible delayed hepatotoxicity and the need to continue administration of *N*-acetylcysteine antidote. In addition, continuous monitoring of serum values permits an accurate pharmacokinetic calculation of the ingested dose (Melethil et al., 1981). Similarly, salicylate serum values related to the time after ingestion may indicate an overdose, providing a prognosis for possible delayed severe metabolic acidosis and the need for lifesaving dialysis treatment. Continuous monitoring of serum salicylate values permits an accurate assessment of the efficacy of dialysis.

Ethanol is the most common chemical encountered in emergency toxicology. Although relatively few fatal intoxications occur with ethanol alone, serum values are important in the assessment of behavioral, physiologic, and neurological function, particularly in trauma cases where the patient is unable to communicate and surgery with the administration of anesthetic or analgesic drugs is indicated. Intoxications from accidental or deliberate ingestion of other alcohols or glycols—such as methanol from windshield deicer or paint thinner, isopropanol from rubbing alcohol, and ethylene glycol from antifreeze—are often encountered in emergency departments. Following ingestion of methanol or ethylene glycol, patients often present with similar neurological symptoms and severe metabolic acidosis due to the formation of toxic aldehyde and acid metabolites. A rapid quantitative serum determination for these intoxicants will indicate the severity of intoxication and the possible need for dialysis therapy. Alcohol infusion, in order to saturate the enzyme alcohol dehydrogenase, blocks the conversion of methanol and ethylene glycol to their toxic metabolites. Continuous monitoring of serum values not only permits an assessment of the clearance of the intoxicant by dialysis, but also assures a proper infusion rate of alcohol for effective antidotal concentrations (Fig. 32-7). To provide effective service to the emergency department, laboratories should have available chromatographic methods for the rapid separation and detection of alcohols and glycols (Edinboro et al., 1993).

The utilization of the analytical capabilities of a clinical toxicology laboratory has increased enormously in recent years. Typically, the laboratory performs testing not only for the emergency department but also for a wide variety of other medical departments, as drugs and toxic chemicals may be a consideration in diagnosis. Urine is analyzed from substance abuse treatment facilities to monitor the administration of methadone or other therapeutic agents and/or to assure that patients do not continue to abuse drugs. Similarly, psychiatrists, neurologists, and physicians treating patients for chronic pain need to know whether patients are self-administering drugs before such patients undergo psychiatric or neurological examinations. Analysis for drugs of abuse in meconium and urine obtained from neonates is used to corroborate the diagnosis of withdrawal symptoms in newborns and document fetal exposure to controlled substances. Toxic metal determinations, such as blood lead concentration, are often performed to assess possible toxic metal exposure or severity of toxicity. Analysis of heavy metals in 24-hour urine specimens is often used to rule out toxic metal exposure as a cause of symmetrical peripheral neuropathy prior to the diagnosis of neurological disorders such as Guillian–Barré syndrome. The clinical toxicology laboratory may often perform unique diagnostic tests that require sophisticated analytical capabilities such as GC-MS and LC-MS analysis for organic acids and amino acids to detect inborn errors of metabolism in infants and children. Methods for the analysis of abnormal organic acids will also detect acidic drugs and other intoxicants such as salicylates, ethylene glycol, GHB, and valproic acid. Another such diagnostic test requiring sensitive chromatography is the timed metabolism of lidocaine to its monoethylglycinexylidide (MEGX) metabolite (O'Neal and Poklis, 1996). The rate of this conversion is a sensitive indicator of hepatic dysfunction and is often used to assess hepatic viability in donor livers prior to transplantation. MEGX formation may also be useful in monitoring the severity of the histological condition of patients with chronic hepatitis and cirrhosis (Shiffman et al., 1994).

ROLE IN THERAPEUTIC MONITORING

Historically, the administration of drugs for long-term therapy was based largely on experience. A dosage amount was selected and administered at appropriate intervals based on what the clinician had learned was generally tolerated by most patients. If the drug seemed ineffective, the dose was increased; if toxicity developed, the dose was decreased or the frequency of dosing was altered. At times, a different dosage form might be substituted. Establishing an effective dosage regimen was particularly difficult in children and the elderly.

The factors responsible for individual variability in responses to drug therapy include the rate and extent of drug absorption, distribution, and binding in body tissues and fluids, rate of metabolism and excretion, pathological conditions, and interaction with other drugs (Blaschke et al., 1985). Monitoring of the plasma or serum concentration at regular intervals will detect deviations from the average serum concentration, which, in turn, may suggest that one or more of these variables need to be identified and corrected.

With multiple administrations of a given drug at regular intervals, plasma drug concentrations will gradually increase and eventually reach a plateau over the course of therapy. The plateau is referred to as a steady-state condition, whereas the amount of drug absorbed is in equilibrium to the amount of drug eliminated. Dosage regimes are calculated so that plasma drug concentrations during steady-state conditions are within the therapeutic range, and monitoring such conditions assures that an effective concentration

Table 32-6

Drugs Commonly Indicated for Therapeutic Monitoring

Antiarrhythmics
Digoxin
Digitoxin
Lidocaine
Procainamide and *N*-acetylprocainamide
Quinidine
Antibiotics
Amikacin
Chloramphenicol
Gentamicin
Tobramycin
Vancomycin
Anticancer
Methotrexate
Anticonvulsants
Carbamazepine
Gabapentin
Lamotrigine
Levetiracetam
Phenobarbital
Phenytoin
Primidone
Topiramate
Valproic acid
Zonisamide
Antidepressants
Amitriptyline and nortriptyline
Doxepin and nordoxepin
Fluoxetine and norfluoxetine
Impramine and desipramine
Paroxetine
Sertraline and desmethylsertraline
Antipsychotics
Clozapine
Pimozide
Bronchodilators
Caffeine
Theophylline
Immunosuppressants
Azathioprine
Cyclosporine
Mycophenolic acid
Sirolimus
Tacrolimus
Mood stabilizing
Lithium

is present. For drugs that have a defined correlation between serum concentrations and undesired toxic effects, the lowest serum concentration immediately prior to dosing (trough) and the highest expected serum concentration (peak) are monitored to assure efficacy and minimize toxicity.

Because the drug being administered is known, qualitative characterization of the analyte generally is not required. Quantitative accuracy is required, however. Frequently, the methodology applied is important, particularly in regard to its selectivity. For example, methods that measure the parent drug and its metabolites are not ideal unless the individual analytes can be quantified separately. Depending on the drug, metabolites may or may not be active to a different degree than the parent drug. The cardiac antiarrhythmic drug procainamide is acetylated during metabolism to form *N*-acetylprocainamide (NAPA). This metabolite has antiarrhythmic activity of almost equal potency to that of the parent drug procainamide. There is bimodal genetic variation in the activity of the *N*-acetyltransferase for procainamide, so that, in "fast acetylators," the concentration of NAPA in the serum may exceed that of the parent drug. For optimal patient management, information should be available about the concentrations of both procainamide and NAPA in serum (Bigger and Hoffman, 1985).

Because absolute characterization of the analyte is not necessary for many drugs, immunoassay procedures are commonly used. This is particularly true of drugs with extremely low serum concentrations, such as cardiac glycosides, and drugs that are difficult to extract because of a high degree of polarity, such as the aminoglycoside antibiotics. In these cases, serum can be conveniently assayed directly by using commercially available kits for immunoassays.

The chromatographic methods in which an appropriate internal standard is added are favored when more than one analyte is to be quantified or if metabolites with structures similar to those of the parent drugs must be distinguished. Because the nature of drugs is varied, many different analytical techniques may be applied, including atomic absorption spectrophotometry for measuring lithium used to treat manic disorders. Virtually all the tools of the analyst may be used for specific applications of analytical toxicology. Drugs that are commonly monitored during therapy are presented in Table 32-6.

SUMMARY

The analytical techniques employed by forensic toxicologists have continued to expand in complexity and improve in reliability and sensitivity. Many new analytical tools have been applied to toxicological problems in almost all areas of the field, and the technology continues to open new areas of research. Forensic toxicologists continue to be concerned about conducting unequivocal identification of toxic substances in such a manner that the results can withstand a legal challenge. The issues of substance abuse, designer drugs, increased potency of therapeutic agents, and widespread concern about pollution, and the safety and health of workers present challenges to the analyst's knowledge, skills, and abilities. As these challenges are met, analytical toxicologists will continue to play a substantial role in the expansion of the discipline of toxicology.

HISTORY OF CLINICAL TOXICOLOGY

Historical Aspects of the Treatment of Poisoning

The history of poisons and poisoners dates back to ancient times. One of the earliest documented uses of poisons was for military use. The use of toxic smoke can be tracked to as early as 2000 BC in ancient India. Formulas for creating poisonous and noxious vapors have also been found from 1000 BC in Chinese writings. The incorporation of fire-generated arsenic-containing smoke from the burning of wood covered with pitch and sulfur containing material was reportedly used by Sparta against Athens around 400 BC (Osius, 1957; Mayor, 2003). Documentation regarding the use of antidotes can be found in the Odyssey and Shastras from approximately 600 BC. What is considered to be the first documented use of a specific antidote may be found in Homer's Odyssey where it is suggested to Ulysses that he take moli to protect himself from poisoning. Moli may actually be *Galanthus nivalis*, a plant-derived cholinesterase inhibitor that might counteract the effects of the anticholinergic plant *Datura stramonium* (Plaitakis and Duvoisin, 1983).

Galen (129 to 200 AD) wrote three books called *De Antidotis I, De Antidotis II,* and *De Theriaca ad Pisonem* that described the development of a universal antidote known as alexipharmic or theriac by King Mithridates VI of Pontus who lived from 132 to 63 BC (Wax, 1997). The antidote reportedly contained 36 or more ingredients that were ingested every day, conferring protection against a broad spectrum of poisons such as venomous stings and bites from vipers, spiders, and scorpions (Jarcho, 1972).

The refinement of theriac (antidote) formulations is documented for nearly 2000 years. Andromachus (1st century AD) was a physician to Nero and improved the Mithridates theriac by modifying the formula to include up to 73 ingredients (Wax, 1997). The use of these ancient antidotes included treatment of acute poisoning and prophylactic treatment to make one "poison proof." The Mithridates theriac with subsequent modifications remained in use until the early 20th century. William Heberden wrote *Antitheriaka: An Essay on Mithridatium and Theriaca* in 1745 in which he questioned the effectiveness of these products (Jarcho, 1972). Despite the skepticism concerning these antidote formulations, their use continued for two millenniums.

One of the earliest writings on the prevention of the gastrointestinal absorption of poisons was by Nicander (Major, 1934). In this ancient writing, the induction of emesis by ingestion of an emetic agent or mechanical stimulation of the hypopharynx was described as a method to prevent poison absorption. It would not be until the 1600s when the use of ipecacuanha for induction of emesis was recommended by William Piso (Reid, 1970).

The use of oral charcoal, now a mainstay in the treatment of many human poisonings, can be dated to early Greek and Roman civilization when wood charcoal was used for the treatment of maladies such as anthrax and epilepsy (Cooney, 1995). The antidotal properties of charcoal were demonstrated in the 1800s by the French with dramatic demonstrations of a reduction in lethality when charcoal was ingested with potentially lethal dosages of arsenic trioxide by Bertrand and strychnine by Touery (Holt and Holz, 1963). One of the earliest reported human studies examining the efficacy of charcoal in poisoning was in 1948 by the American physician Rand (Holt and Holz, 1963). As recently as the early 1960s, poison treatment center employees were known to start their workday by burning toast to create a supply of poison absorbent (charcoal) for the day's

*Deceased

work. The use of superheated steam to treat the charcoal to enhance its absorption capacity was reported by Ostrejko, a Russian scientist in 1900 (Greensher et al., 1987). By the 1960s, the use of activated charcoal became routinely recommended for the treatment of patients poisoned with substances thought to be adsorbed by charcoal.

Modern Development of Effective Antidotes for Poisoning

The search for safe and effective antidotes has been challenging to say the least. From the time of the early, self-experimenting proponents of effective antidotes to as recently as the later part of the last century, discovery, refinement, and determination of conditions to permit optimal use of antidotes has been less than ideal. Much the same could be said for the state of drug development more broadly during the same time period. It was not until the mid-20th century that a more informed scientific and systematic approach to drug development became possible and, in fact, became a requirement by newly created regulatory agencies in charge of controlling the sale and distribution of medicinal products.

The therapeutic area of poison treatments and prophylaxis presents several additional hurdles compared to drug development for other, more prevalent disease categories. These challenges include the inability to perform controlled human studies to evaluate efficacy, in part due to the small numbers of poisoned patients available for enrollment in therapeutic trials and also due to the often-sporadic occurrence of specific poisonings. These realities make it difficult to easily perform acceptable evaluations of poisoning antidotes. In addition, when trying to transition the nonclinical data for poison treatments to humans, there are sometimes significant interspecies differences encountered that make extrapolation of experimental efficacy or safety findings difficult. In recognition of these challenges, in 2002 the Food and Drug Administration enacted the Animal Efficacy Rule, which allows FDA to approve products for serious or life-threatening conditions caused by exposure to lethal biological, chemical, radiological, or nuclear substances without human efficacy testing. The rule allows the sponsor of the product to demonstrate adequate efficacy of the product in a valid animal or in vitro model of the toxicity and not humans, for obvious ethical or in the setting of an infectious outbreak, logistic reasons. The human safety data is then determined by controlled clinical trials that involve administration of therapeutic dosages of the chem/bio/rad treatment agent in the absence of the poisoning to healthy volunteers (Gaffney, 2015).

INTRODUCTION OF THE POISON CONTROL CENTER

Advances in the field of clinical toxicology and improvements in the quality of care of the poisoned patient have paralleled the evolution of poison control centers (PCCs). The introduction of the poison center and subsequent formation of associations involving healthcare professionals who work in these centers brought with it an opportunity to share information through publications and national conferences that ultimately resulted in systematic enhancements in the treatment of the poisoned patient. One of the earliest local efforts to systematically collect, analyze, and distribute to physicians, clinical information about poisoning was led by Jay Arena, MD, a Duke University pediatrician. In 1939, he published a case series detailing the clinical outcome of 50 cases of lye poisoning (Martin and Arena, 1939). Interest in clinical information regarding the treatment of poisoned patients and resultant patient outcomes was also growing in Europe during approximately the same time. During the 1940s, several European communities developed hospital-based treatment facilities for poisoning (Manoguerra and Temple, 1984). This local poison information effort continued for several years as further realization of the growing importance of the problem of poisoning was appreciated. A study by the American Academy of Pediatrics completed in 1952 reported that more than half of childhood accidents involved unintentional poisoning in the United States. Possibly in response to this study, Edward Press, MD, and Louis Gdalman, RPh, started the first United States poison control center (PCC) in Chicago, Illinois in 1953. Mr Gdalman collected toxicological information on more than 9000 commercial and noncommercial products throughout the 1940s and early 1950s. Their Chicago poison center provided telephone advice to healthcare professionals as well as collected poisoning data systematically during the telephone exchange. As more centers were created they grew to become valuable resources for information about product ingredients, potential toxicity, and recommendations for the treatment of poisoned patients. PCCs proliferated over the next two decades and peaked at 661 centers in 1978 (Scherz and Robertson, 1978). At the peak of this proliferation, each state in the United States had at least one poison center; several states had more than 20 poison centers active at the same time, but there was little standardization throughout the specialty. Information resources gradually evolved from collected experiences of the individual poison center to a centralized collection of product contents, toxicities, and recommended treatments provided in a microfiche database to today's Internet-based globally available database that is frequently updated and incorporates consensus recommendations for various treatment protocols for specific poisonings. Through regionalization, consolidation, and certification, the number of PCCs decreased significantly over time to 55 centers in 2015 (Mowry et al., 2016).

Today, poison centers are generally staffed by a medical director (Medical Toxicologist), administrator or managing director, specialists in poison information, and educators for poison prevention programs. The medical toxicologist, managing director, and specialists in poison information are healthcare professionals who are credentialed by their respective boards. The American Board of Medical Subspecialties offers a subspecialty certificate in Medical Toxicology to physicians who successfully complete the certifying examination. The American Board of Applied Toxicology (ABAT) offers a certification examination for nonphysicians and the American Association of Poison Control Center (AAPCC) provides a certification of the specialists in poison information who are usually nurses, pharmacists, or other healthcare personnel. The managing director of the poison center is usually either the same person as the medical director or a nonphysician certified by the ABAT. The nonphysician toxicologists are referred to as clinical toxicologists.

Poison centers provide a significant service to the general public and to practicing healthcare providers. These services include direct information to patients with expert recommendations for needed treatment, critical diagnostic and treatment information for healthcare professionals, education for healthcare personnel, and poison prevention activities through public education. In recognition of this valuable service, the "Poison Control Center Enhancement and Awareness Act" was signed in 2000, which ensured that all citizens had toll-free access to a PCC, and it was subsequently amended to include partial federal funding in 2008 in part to serve as an early-warning system for potential chemical, biological, or radiologic terrorist attacks (Woolf et al., 2011). This funding was

recently extended through 2019 (Rep. Terry, 2014). Central data collection via the National Poison Data System (NPDS) in near real time has demonstrated the capability for the PCC network to serve in the early warning role (Wolkin et al., 2012). Recent reporting from this network shows that poisoning case data from PCCs are uploaded every 8 minutes on average supporting this role on a national level (AAPCC, 2017).

In addition to this public health alert capability, the ability for PCCs to provide data that can lead to the recognition of improper use of medications, emergence of new illicit drug exposures or practice, prescription product diversion, and product tampering events has been demonstrated. Several examples can be found that indicate that public access to a certified PCC is cost effective, in terms of overall healthcare expenditures. One early publication documented the economic consequence of a 1-year forced closure of the Louisiana State Poison Center several years ago. Without a poison center to call, residents of the community were left with the expensive alternative of visiting a nearby hospital's emergency room or doctor's office visit for possible treatment of their exposure. It was estimated that the increased costs to the state for emergency medical services (EMS) were $1.4 million for that year (King and Palmisano, 1991). Since that study, several other studies have shown that for each dollar spent to operate a PCC, a savings of approximately $3 to $7.67 can be realized for the healthcare system (Miller and Lestina, 1997; Blizzard et al., 2008).

In 2004, the Institute of Medicine (IOM) affirmed the value and need for a poison center system by their commissioned in-depth study of poison prevention and control services in the United States. Their report (IOM, 2004) recommended further standardization of the regional poison centers, partial federal funding for the poison center system to stabilize core functions of each center, and integration of PCCs with public health agencies at the federal, state, and local level including integration with the Centers for Disease Control and Prevention for chemical and biological terrorism preparedness. Since that time, other reports have shown the cost-benefit value of the national poison control system for these functions (Lewin Group, 2012).

CLINICAL STRATEGY FOR THE TREATMENT OF THE POISONED PATIENT

The setting for the initial treatment of a seriously poisoned patient is usually in a hospital emergency room but can sometimes be in other, less ideal settings such as the battlefield, workplace, home, or street setting. In treatment environments that permit a complete assessment and initiation of treatments, most clinical toxicologists agree that a methodically executed, stepwise approach for the evaluation and treatment of the poisoned patient is recommended for optimal care (Ellenhorn, 1997a, 1997b; Hoffman, 2015). In this section, an overview of the general approach to the treatment of poisoned patients in the emergency department (ED) or acute intensive care setting of a hospital will be described. Please note that once the patient is relatively stabilized, the early steps listed often are initiated in parallel. In that setting, the following general steps represent important elements of the initial clinical encounter for a poisoned patient:

1. Clinical stabilization of the patient
2. Clinical evaluation (history, physical, laboratory, radiology)
3. Prevention of further toxicant absorption
4. Enhancement of toxicant elimination
5. Administration of antidote (if available)
6. Supportive care, close monitoring, and clinical follow-up

Clinical Stabilization

The first priority in the treatment of poisoning is to stabilize the patient. Assessment of the patient's airway (ability to move air into and out of the lungs), breathing (the presence of spontaneous respirations), and circulation (adequate blood pressure and perfusion of vital organs) is the initial step of emergency treatment. Some poisoned patients, soon after even a potentially lethal exposure of the toxicant has occurred, will not show significant symptoms. Most poisoned patients, with a toxic exposure, will exhibit symptoms early in their presentation. For this reason, the initial triage of a poisoned patient can be difficult. On occasion, the patient is asymptomatic on presentation but by history has had a potentially serious toxic exposure. Clinicians and medical support staff, who may not be knowledgeable about the toxic exposure level of a specific drug or chemical, may mistakenly stratify the patient to a lower treatment priority, which can have disastrous results. The improper stratification sometimes can include a delay in calling for a clinical toxicology consultation from a regional PCC or a regional poison treatment center. Some drugs, such as a benzodiazepine, can cause significant sedation early after exposure but often have a comparatively mild clinical course, whereas other chemicals, such as camphor, show little clinical effects initially but can produce a fatal outcome. Some chemicals and drugs can cause seizures as part of their toxic-effect profile. Control of drug/toxicant-induced seizures can be an important component of the initial stabilization of the poisoned patient. A full discussion of the various methods available to treat abnormal conditions with a patient's airway, breathing, circulation, and control of toxicant-induced seizures is beyond the scope of this chapter. The reader is referred to textbooks of *Emergency Medicine and Critical Care Medicine* for further information on this subject. After the initial stabilization of the patient, the remainder of the assessment and treatment steps can proceed. On occasion, especially in critically ill patients, treatment interventions are initiated before a patient is completely stable.

Clinical History in the Poisoned Patient

The primary goal of obtaining the medical history in poisoned patients is to determine the substance the patient was exposed to and the extent and timing of exposure. Unfortunately, in contrast to most specialties of medicine, the clinical history from the initial clinical encounter with the poisoned patient is sometimes not available because either the patient is unresponsive and unable to provide the history or the history provided is unreliable. The history may be unreliable due to the inability of the patient to recall pertinent facts relating to the ingestion or exposure, or in the setting of an attempted suicide or a patient who has taken illegal substances, the patient often is not willing to provide an accurate history. For these reasons, additional sources for the clinical history are often incorporated to aid the clinical team in determining the exposure history. Examples of additional resources sometimes employed to obtain an informative clinical history include interviewing family members and emergency medical technicians who were at the scene, searching an electronic medical record, or contacting a pharmacist who can sometimes provide a listing of prescriptions recently filled or an employer who can provide a list of chemicals found in the work environment for an occupational exposure. Many times, identification of the exact substance responsible for the observed toxic effects is not known for hours to days after the ingestion, or on occasion detected during autopsy in fatal cases.

When estimating the extent of exposure to the poison, it is generally recommended that one maximize the estimated dose received. That is, one should assume that the entire contents of the

prescription bottle were ingested, that the entire bottle of liquid was consumed, most of the body surface area was exposed to a topical chemical, or that the highest possible concentration of airborne contaminant was present for a patient poisoned by inhalation unless definite evidence exists to the contrary. Maximizing the potential dose or exposure level allows one to prepare adequately for the worst-case scenario, that is, the most clinically severe manifestations of the poisoning rather than underestimating the exposure and therefore the anticipated toxic effects and, as a result, be unprepared for a serious clinical presentation in a poisoned patient.

Once an appropriate estimate of the dose is made, the toxicologist can refer to various information resources to determine what the range of expected clinical effects might be from the estimated exposure. This is one of the most important early functions of the poison center. The estimation of expected toxicity greatly assists with the triage of poisoned patients. Poison information specialists working in the PCCs routinely give telephone recommendations regarding the level of medical care required for a given ingestion based on the expected clinical effects from the reported ingestion. The majority of in-the-home accidental pediatric exposures are treated with at-home observation and occasionally with the additional recommendation for home-administered activated charcoal if readily available. In the hospital setting, ED staff use the estimation of expected clinical effects to effectively triage the poisoned patient. For example, a 3-year-old patient who accidentally ingested 25 children's chewable multivitamins without iron would likely be triaged to a noncritical care area of the ED, whereas another similar patient who ingested a large amount of a potent anticholinergic medication would be triaged to a high-intensity care section of the ED.

Estimating the timing of the exposure to the poison is frequently the most difficult aspect of the clinical history when treating the poisoned patient. Often the toxicologist must turn detective to determine the most likely window of time that the exposure occurred. For example, if a pediatric patient was being watched by a baby-sitter at all times except for a 20-minute period that preceded the onset of symptoms and the discovery of an open prescription bottle for a calcium channel blocking agent is found, then it is straightforward to assume that the ingestion occurred in that 20-minute window. Other situations require estimation of a far broader window for exposure. For a person found down with several empty prescription bottles nearby who was not seen by anyone for the preceding 24 hours, one would not be able to accurately estimate the time of ingestion other than sometime in that 24-hour window. Therefore, in view of these often-encountered limitations, obtaining an accurate history in the poisoned patient can be very challenging and occasionally completely lacking. When the history is unobtainable or unreliable, the treating clinical toxicologist is left in the setting of empirical treatment of an "unknown ingestion" poisoning. This type of treatment will be discussed later in this chapter.

Physical Examination

One of the most important actions performed during the initial clinical encounter in the treatment of the poisoned patient is the physical examination. A thorough examination of the patient is required to assess the patient's condition, determine the patient's mental status, and, if altered, determine possible nontoxicology explanations for the abnormal mental status such as trauma or central nervous system infection. In addition, findings from the physical examination allow one to categorize the patient's physical examination parameters into broad clinical presentation classes referred to as toxic syndromes. These toxic syndromes have been called toxidromes (Mofenson and Greensher, 1970; Holstege and Borek, 2012; Hoffman, 2015). A toxidrome is a constellation of clinical signs and symptoms that, when taken together, are likely associated with exposure from certain toxicological classes of chemicals. The major toxic syndromes include narcotic, cholinergic, sympathomimetic, anticholinergic, sedative-hypnotic, and withdrawal from ethanol/sedative-hypnotics and withdrawal from opioids. Table 33-1 lists the clinical features of these major toxic syndromes.

Table 33-1

Clinical Features of Toxic Syndromes

	BLOOD PRESSURE	PULSE	TEMPERATURE	PUPILS	LUNGS	ABDOMEN	NEUROLOGICAL
Sympathomimetic	Incr.	Incr.	Slight Incr.	Mydriasis	NC	NC	Hyperalert, incr. reflexes
Anticholinergic	Slight incr. or NC	Incr.	Incr.	Mydriasis	NC	Decr. bowel sounds	Altered mental status
Cholinergic	Slight decr. or NC	Decr.	NC	Miosis	Incr. bronchial sounds	Incr. bowel sounds	Altered mental status
Opioid	Decr.	Decr.	Decr.	Miosis	NC or rales (late)	Decr. bowel sounds	Decr. level of consciousness
Ethanol-sedative hypnotics	Decr.	Decr.	Decr.	Variable	NC	Decr. bowel sounds	Agitation; decr. level of consciousness
Withdrawal from ethanol-sedative hypnotics	Incr.	Incr.	Incr.	Mydriasis	NC	Incr. bowel sounds	Agitation; hallucinations; seizures
Withdrawal from opioids	Incr.	Incr.	Variable	Mydriasis	NC	Incr. bowel sounds; vomiting	Anxious, piloerection

In certain treatment settings, the precise agent responsible for the poisoning is not known during the critically important phase of initial treatment of the poisoned patient. When the treating physicians are able to categorize the patient's presentation into a toxic syndrome, it permits initiation of rationale treatment based on the most likely category of toxicant responsible without knowing the specific chemical causing the poisoning. For example, if a patient presents with altered mental status, mydriasis (dilated pupils), mild hypertension, tachycardia, warm skin, dry mucous membranes, and diminished bowel sounds in the abdomen, the clinical toxicologist can characterize the patient's presentation as consistent with the anticholinergic toxic syndrome. The treatment would then be directed at support of respiration and potentially administering a pharmacological antidote like physostigmine as well as additional situation-requiring supportive care.

Occasionally, a characteristic odor can be detected on the poisoned patient's breath or clothing, which may point toward exposure or poisoning by a specific chemical. Table 33-2 lists some of the better-recognized odors and the substance associated with the odor. Detection of one of these odors may provide an important historical clue as to the agent responsible for the poisoning.

Periodic re-examination of the patient is a very important aspect of clinical toxicology treatment procedures. Follow-up clinical examinations can help gauge the progression of the clinical course of poisoning as well as determine the effectiveness of treatment interventions and assess the need for additional treatment procedures.

Laboratory Evaluation

A common misconception concerning the initial treatment of poisoned patients is that a definitive diagnosis of the specific agent or poison responsible for the patient's clinical presentation is frequently made based upon clinical laboratory testing in real time. Unfortunately, the availability of an assay to identify the specific drug or industrial chemical on a rapid turn-around basis (STAT, e.g., within 1 hour) is very limited. Table 33-3 lists drugs or other chemical tests that are typically available for STAT measurement in a medical center-type hospital facility (UCSF, 2017). As one can see, the number of chemicals for which quantitative detection is possible in a rapid turn-around timeline is extremely limited, compared to the large number of possible chemicals that can poison patients. This further emphasizes the importance of recognizing clinical syndromes for poisoning and for the clinical toxicologist to be able to initiate general treatment and supportive care for the patient with poisoning from an unknown substance.

For the relatively few chemicals that can be quantified on a rapid turn-around basis in an ED setting, the quantitative measurement can often provide both prognostic and therapeutic guidance. Several authors have suggested certain "action levels" for specific therapeutic drugs and chemicals, which when met or exceeded in the patient's plasma should trigger specific interventions or predict likely clinical outcomes. In some cases, measurement of an indicator of the biological effect of a poison provides sufficient information to render definitive treatment to the patient. Measurement of methemoglobin concentration in a patient poisoned by one of many chemicals that can cause this chemical transformation of the hemoglobin molecule is sufficient to initiate treatment for methemoglobinemia without identification of the specific toxicant that caused the condition. Similarly, most hospital laboratories have the capability for rapid measurement of carboxyhemoglobin concentrations, which permits treatment of carbon monoxide poisoning based on the laboratory test measuring a surrogate marker for carbon monoxide exposure.

For some commonly ingested drugs, a nomogram has been established to predict the severity of the poisoning and is important in some cases to guide therapeutic intervention based on the measured plasma concentration of the drug and the time elapsed from the expose. Proper use of such nomograms is necessary for the clinical management of poisoning cases where available.

The clinical usefulness of a drug plasma concentration measured by the clinical laboratory was suggested for salicylates approximately 50 years ago. In 1960, Done published a nomogram to predict the clinical outcome from poisoning with salicylates (Done, 1960). After years of routine clinical use, further investigation led to the conclusion that the clinical utility of the Done nomogram was insufficient to recommend continued applicability to human salicylate poisoning. As a result, use of this nomogram in practice is no longer recommended (Dugandzic et al., 1989; American College of Medical Toxicology, 2015).

In 1975, Rumack and Matthew published a nomogram for acetaminophen poisoning shown in Fig. 33-1 (Rumack and Matthew, 1975). This nomogram predicts clinical outcome and has maintained

Table 33-2

Characteristic Odors Associated With Poisonings

ODOR	POTENTIAL POISON
Apple blossoms	Chloroacetophenone (tear gas)
Bitter almonds	Cyanide
Carrots	Cicutotoxin (water hemlock)
Eggs	Hydrogen sulfide, mercaptans
Garlic	As, organophosphates, DMSO, thallium
Mothballs	Naphthalene, camphor
Pear-like	Paraldehyde, chloral hydrate
Rotten eggs	Hydrogen sulfide, mercaptans, *N*-acetylcysteine
Vinyl	Ethchlorvynol
Wintergreen	Methylsalicylate

Abbreviation: DMSO, dimethyl sulfoxide.

Table 33-3

List of Tests that Are Commonly Measured in a Hospital Setting on a STAT Basis

Acetaminophen	Osmolality
Carbamazepine	Phenobarbital
Carboxyhemoglobin	Phenytoin
Digoxin	Procainamide/NAPA
Ethanol	Quinidine
Gentamicin	Salicylates
Iron	Theophylline
Lithium	Tobramycin
Magnesium	Valproic acid
Methemoglobin	Vancomycin

Abbreviation: NAPA, N-acetylprocainamide.

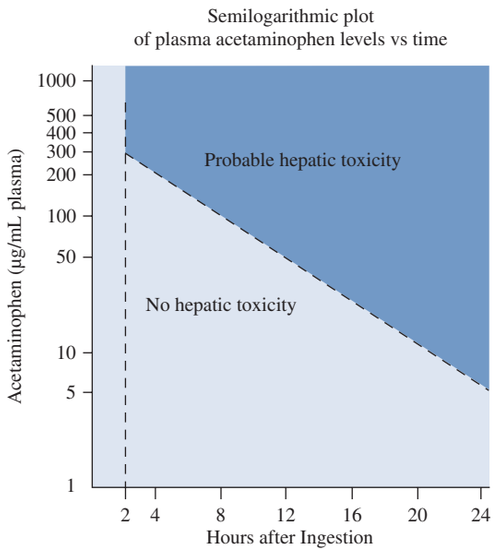

Figure 33-1. *Rumack–Matthew nomogram for acetaminophen poisoning.* (From Rumack and Matthew [1975], with permission. Copyright American Academy of Pediatrics [1975].)

its clinical utility over time as a valuable tool to guide the clinician in the decision as to whether or not to administer *N*-acetylcysteine (NAC), an antidote for significant acetaminophen ingestion. Laboratory evaluation of a patient potentially poisoned with acetaminophen is crucial to assess what hepatic injury may have already occurred and to determine the plasma concentration of acetaminophen for prognostic purposes. Accurate estimation of acetaminophen in the plasma should be done on samples drawn at least 4 hours after ingestion, when or past the time that peak plasma levels can be expected. Once an accurate plasma concentration of acetaminophen has been obtained at least 4 hours post ingestion, it should be plotted on the Rumack–Matthew nomogram (Fig. 33-1) to determine whether NAC therapy is indicated. This nomogram is based on a series of patients with and without hepatotoxicity and their corresponding acetaminophen plasma concentrations at presentation.

In the appropriate patient, the decision to treat an acetaminophen-poisoned patient is based on the plasma concentration of parent acetaminophen plotted on the nomogram. Although some authors recommend that NAC treatment only be administered to a patient with an acetaminophen plasma concentration in the "definite toxic" range, many clinical toxicologists agree that NAC should be given at or above the "probably toxic" action level due to the often present uncertainty in the clinical history with respect to the exact time of the ingestion. It should be noted, however, that proper use of this nomogram is required, namely that certain conditions should be met to apply the nomogram to a specific clinical case. The nomogram was validated for a single acetaminophen ingestion, the time of ingestion is critically important to establish the X-axis coordinate for the data point and the plasma concentration should have been obtained at least 4 hours after ingestion to assure that the peak plasma concentration of parent acetaminophen has occurred.

Similar, though, perhaps less well established, predictive relationships of drug plasma concentration and clinical outcome and/or suggested concentrations that require therapeutic interventions are available for several other drugs including lithium, digoxin, iron, phenobarbital, and theophylline. Some authors have identified "action levels" or toxic threshold values for the measured plasma concentrations of various drugs or other chemicals (Ellenhorn, 1997a, 1997b). Generally, these values represent mean concentrations of the respective substance that have been shown to produce a significant harmful effect during a retrospective analysis of clinical case series. However, the pharmaco- (or toxico-) dynamic variability for a given toxicant or for a combination of toxicants is significant. For example, a patient with a "normal" or "nontoxic" digoxin level may display significant toxic effects and conversely a patient with an elevated or "toxic" plasma concentration of digoxin may not show any sign of harmful effects. The clinical toxicologist is required to critically evaluate the measured drug concentration in context of the clinical presentation of the patient and not react to the measured laboratory value alone. An additional confounding factor is the often-encountered co-ingestion of another substance in the poisoning. The applicability of exposure-response models to predict clinical severity in the presence of a second or multiple toxicants is unknown.

Because of the limited clinical availability of rapidly available "diagnostic" laboratory tests for poisons (Table 33-3), toxicologists can sometimes gain important insight into what potential drugs were ingested by performing simple calculations based on routine clinical laboratory data. Two examples of these laboratory-derived methods to potentially identify what substance was ingested are the anion gap (AG) and the osmol gap calculations. An elevated AG or osmol gap suggests a finite differential diagnosis for significant exposures in a poisoned patient. Both calculations are used as diagnostic aids when the clinical history suggests poisoning and the patient's condition is consistent with exposure to chemicals known to cause elevations of these parameters.

The AG is calculated as the difference between the serum Na ion concentration and the sum of the serum Cl and HCO_3 ion concentrations.

$$\text{AG} = [\text{Na mEq/L} - (\text{Cl mEq/L} + \text{HCO}_3\text{ mEq/L})]$$

$$\text{Normal AG} \leq 12$$

When there is laboratory evidence of metabolic acidosis (low blood pH and low serum HCO_3) in a poisoned patient, the finding of an elevated AG would suggest systemic toxicity from a relatively finite list of chemicals. A popular clinical mnemonic (AT MUD PILES) is commonly employed as a memory aid for this differential diagnosis. Table 33-4 lists the more common chemicals that have metabolic acidosis with an elevated AG as part of the clinical presentation that are included in this pneumonic. Additional substances not included in this table, such as benzyl alcohol, carbon monoxide, hydrogen sulfide, metformin, phenformin, formic acid, and other organic or mineral acids, as well as the anti-seizure medication valproic acid, can also result in elevated AG with systemic metabolic acidosis.

The second calculated parameter from clinical chemistry values is the osmol gap. The osmol gap is calculated as the numerical difference between the measured serum osmolality and the serum osmolarity calculated from the clinical chemistry measurements of the serum sodium ion, glucose, and blood urea nitrogen (BUN) concentrations (Smithline and Gardner, 1976).

$$\text{Osmol gap} = \text{measured serum osmolality (mOsm)} - \text{calculated serum osmolarity (mOsm)}$$

where calculated serum osmolarity = 2 × Na mEq/L + glucose mg/dL/18 + BUN mg/dL/2.8

$$\text{Normal osmol gap} < 10\text{ mOsm}$$

Table 33-4

Differential Diagnosis of Metabolic Acidosis with Elevated Anion Gap: "AT MUD PILES"

A	Alcohol (ethanol ketoacidosis)
T	Toluene
M	Methanol
U	Uremia
D	Diabetic ketoacidosis
P	Paraldehyde
I	Iron, isoniazid
L	Lactic acid
E	Ethylene glycol
S	Salicylate

Table 33-5

Differential Diagnosis of Elevated Osmol Gap

Methanol
Ethanol
Ethylene glycol
Isopropanol
Dimethyl sulfoxide (DMSO)
Mannitol
Propylene glycol

Note that the serum osmolality must be measured by freezing point depression and not boiling point elevation as the latter method can fail to detect the osmolality contribution of volatile, low-molecular-weight substances due to vaporization of the substance during measurement.

An elevated osmol gap in the setting of a poisoned patient suggests the presence of an osmotically active substance in the plasma that is not accounted for by the Na, glucose, or BUN concentrations. Table 33-5 lists several substances that when ingested can be associated with an elevated osmol gap in humans.

Although calculation of both the AG and the osmol gap can provide very useful information from readily available clinical chemistry measurements, these determinations must be interpreted cautiously in certain clinical settings. For example, even though a patient may have ingested a large, significantly toxic amount of methanol, if measured late in the clinical course of the exposure, the osmol gap may not be significantly elevated as most of the osmotically active methanol has left the plasma and has been biotransformed or cleared but is still producing serious clinical effects.

Radiographic Examination

The utility of the plain x-ray radiographic examination to diagnose specific poisonings is relatively limited. This is due primarily to the lack of radiopacity of many oral forms of medication. Sometimes orally ingested toxicants can be visualized radiographically, depending on the specific substance ingested. Early radiographic surveys of the radiopacity of oral medications revealed that the vast majority of commercially available tablets and capsules surveyed were essentially undetectable by a radiograph (Handy, 1971; O'Brien et al., 1986). These and other studies have shown that relatively few formulations of drugs are radiopaque and would likely be detectable by plain x-ray of the abdomen. Generally, plain radiographs can detect a significant amount of ingested oral medication containing ferrous or potassium salts. However, a study of the in vitro and in vivo visualization of chewable oral formulations of iron supplements showed that once the chewable iron was ingested, it was no longer detectable by plain abdominal radiograph (Everson et al., 1989). However, certain formulations that have an enteric coating or certain types of sustained release products are radiopaque and can be visualized (Savitt et al., 1987; Nelson et al., 1993).

The most useful radiographs ordered during the initial management of the poisoned patient include the chest and abdominal radiographs and the computed head tomography study. For example, the abdominal radiograph has been used to detect recent lead paint ingestion in children due to pica for many years. Although the presence of radiographic evidence of lead-based paint chips probably underrepresented the proportion of children with moderate-to-severe lead poisoning in one study, an abdominal radiograph showing pica was associated with significantly elevated blood lead concentrations (McElvaine et al., 1992). Another situation in which an abdominal radiograph may be helpful is the setting of the ingestion of a halogenated hydrocarbon such as carbon tetrachloride or chloroform. If a sufficient amount of either liquid is ingested, it is likely that these organic solvents will be visualized as a radiopaque liquid in the gut lumen on the abdominal film relatively recently after ingestion (Dally et al., 1987). Finally, abdominal plain radiographs have been helpful in the setting where foreign bodies are detected in the gastrointestinal tract. The most common example of this is found when a toddler is being evaluated for potential oral ingestion of a foreign body, such as a watch battery. Early detection by plain radiograph is essential to localize the battery to determine which interventional approach is recommended (Kramer et al., 2015). Another example of an important use of radiography in the acute management of the poisoned patient is during the evaluation of an international traveler to the United States who becomes acutely ill with signs of severe sympathomimetic excess and numerous foreign bodies are visualized throughout the gastrointestinal tract. This type of patient is referred to as a body packer who smuggles illegal substances, such as cocaine (as in this case) or heroin, by swallowing latex or plastic storage vesicles filled with the substance (McCarron and Wood, 1983; Beerman et al., 1986; Sporer and Firestone, 1997). Occasionally, these storage devices rupture and the drug is released into the gastrointestinal tract with serious and sometimes fatal results. Aside from these relatively uncommon situations, the overall clinical utility for detection and diagnosis of poisons by radiography is limited.

In contrast to the limited clinical utility of plain radiography for the identification of a specific poison or to diagnose poisoning, plain radiography and other types of diagnostic imaging in clinical toxicology can be extremely valuable for the diagnosis of toxicant-induced pathology and to aid the clinical toxicologist in the ongoing treatment and patient-management phases of the drug overdose. Detection of drug-induced noncardiac pulmonary edema as seen in some cases of serious intoxication with salicylates and opioid agonists is an example of this occurrence (Stern et al., 1968; Heffner et al., 1990). Plain chest radiography can detect this abnormality, which would likely correlate with the findings observed during physical examination of the lungs. This radiographic finding would increase the severity stratification of the poisoning case and likely alter the planned therapeutic strategy for the patient.

Another example of the use of radiological imaging in clinical toxicology is with computed tomography (CT) of the brain. Significant exposure to carbon monoxide (CO) has been associated with focal CT lesions of the brain consisting of low-density areas,

also referred to as lucencies in the cerebral white matter and in the basal ganglia, especially the globus pallidus. This finding is not specific for CO poisoning and may be seen with other intoxications and disease conditions that cause relative hypoxemia or hypoglycemia. In the setting of CO intoxication however, these CT findings in the brain can be useful for estimating the prognosis for a patient who survives the initial phase of CO poisoning (Miura et al., 1985; Jones et al., 1994). Similar correlations have been shown with magnetic resonance imaging (MRI). Finally, concurrent intracranial pathology, such as trauma or hemorrhage, can be detected by CT or MRI of the brain to aid in the diagnosis of additional injury or pathology previously not appreciated during the early phases of treatment of the poisoned patient.

The initial clinical evaluation of the poisoned patient is a critically important phase of the therapeutic process to treat poisoned individuals. The physical, laboratory, and radiological examination all contribute to the initial diagnostic steps for poison treatment. The physical and laboratory examinations are generally utilized more from a diagnostic and acute management standpoint, whereas the radiological examination, with the exception of visualization of foreign bodies or radiopaque toxicants, tends to be more useful for detection and management of toxicant-induced pathology.

Prevention of Further Poison Absorption

During the early phases of treatment of a poisoned patient who has had a toxic exposure via the oral, inhalation, or the topical route, the opportunity to prevent further absorption of the poison to minimize the total amount of chemical that reaches the systemic circulation may be possible. For chemicals presented by the inhalation route, the main intervention to prevent further absorption is removal of the patient from the environment where the toxicant is found and to provide adequate ventilation and ensure oxygenation for the patient. For topical exposures, patient clothing containing the chemical must be removed and properly disposed in airtight wrappings or containers to ensure that the rescuers and healthcare providers are adequately protected from secondary exposure. Most topical exposures require gentle washing of the skin with water and mild soap taking care not to cause cutaneous abrasions of the skin that may enhance dermal absorption (Burgess et al., 1999; Braue et al., 2008).

The optimal time to intervene to prevent continued absorption of an oral poison is as soon as possible after the ingestion. Four primary methods are currently available for this purpose: induction of emesis with syrup of ipecac, gastric lavage, oral administration of activated charcoal, and whole-bowel irrigation. Historically, induction of emesis was accomplished by a variety of concoctions such as tartar emetic, an antimony salt, mustard mixed in water, concentrated solutions of copper and zinc salts, and various botanical substances. In hospitals, apomorphine injection was given even in the 1980s to cause emesis in patients with a history of potentially toxic ingestion. Since the 1980s, the primary agent used to induce emesis to treat an oral ingestion of a potential toxicant is syrup of ipecac. This product is available as an over-the-counter (OTC) emetic in the United States since 1965 and, although a mainstay for poison center-directed induction of emesis for decades, today the agent is rarely used to treat poisonings. The reason for the decline in use is primarily the recognition of the overall low, and highly variable, effectiveness for syrup of ipecac as an agent for gastric decontamination (Auerbach et al., 1986). In addition, reports of the potential adverse effects associated with ipecac use gained wider recognition, especially in terms of the risk for aspiration of gastric contents. Additionally, there were data to suggest that the administration of syrup of ipecac could result in a delay in the administration of activated charcoal, thought to be a more effective agent for prevention of oral absorption of toxicants, as discussed below. The American Academy of Clinical Toxicology and the European Association of Poisons Centres and Clinical Toxicologists issued a position paper regarding the use of syrup of ipecac (Krenzelok et al., 1997) followed by an additional, similar consensus publication in 2004 (Krenzelok et al., 2004), which stated that the syrup of ipecac should not be used routinely in the management of the poisoned patient and that there was insufficient data to either support or exclude ipecac administration soon after poison ingestion. Many clinical toxicologists believe that there remains a limited role for the clinical use of syrup of ipecac, mainly in rural areas where the length of time before a poisoned patient can reach medical care is significant, especially when the substance ingested is poorly adsorbed to activated charcoal, as discussed below. Examples of substances poorly absorbable to activated charcoal include ethanol and other alcohols, ethylene glycol, potassium, mineral acids, iron and other metals (variable), and halides such as fluoride. The accepted contraindications for use of syrup of ipecac are (1) children less than 6 months of age; (2) in the ingestion of a caustic agent (acid or alkali); (3) in a patient with a depressed level of consciousness or gag reflex or when the toxicant ingested is expected to cause either condition within a short period of time; or (4) when there is a significant risk of aspiration of gastric contents such as for ingestion of a liquid hydrocarbon with high aspiration potential.

The use of gastric lavage, the technique of placing an orogastric tube into the stomach and aspirating fluid then cyclically instilling fluid and aspirating until the effluent is clear, has also diminished in recent years. The reasons for the decline in the use of this technique include a growing appreciation of the risk of aspiration during the lavage procedure and evolving evidence that the overall clinical effectiveness of gastric lavage may be more limited than originally thought. Like induction of emesis, where the efficacy of the procedure declines with increasing time interval between the use of the procedure and the time of ingestion, gastric lavage too appears to have this important limitation (Vale and Kulig, 2004). Many toxicologists agree that if gastric lavage is to be used, to optimize effectiveness, it should be performed within 1 hour of ingestion of the oral poison. It is more likely to be recommended if the patient ingested a highly toxic substance, especially in the cases where it is likely that activated charcoal will not be effective for the substance ingested. Careful attention to the patient's gag reflex prior to initiation of this procedure is important. If the patient does not exhibit a gag reflex, then endotracheal intubation must be performed to adequately protect the airway and prevent aspiration. It is essential that the orogastric tube be of sufficient size (36 to 40 French for an adult; 22 to 28 French for a child) to be useful. Even with a large bore orogastric tube some tablets or capsules may not be able to pass through the tube. In the pediatric patient, there are practical limitations to the use of large bore tubes. In this case, orogastric lavage may only be useful to attempt removal of liquid toxicant or possibly dissolved tablets or capsules.

As described earlier, the medicinal use of charcoal to prevent the absorption of orally ingested toxins dates back more than 150 years. The first reported medicinal use of oral charcoal to adsorb an ingested toxicant is credited to the American physician, Hort, who, in 1834, used large amounts of powdered charcoal to successfully treat a patient poisoned with a chloride salt of mercury. A dramatic demonstration of the adsorptive effect of oral charcoal was that by Tourey, a French pharmacist who reportedly mixed a lethal dose of strychnine with charcoal and consumed the combination before

his colleagues at the French Academy in 1930 (Andersen, 1946). Early in vitro investigations of the adsorptive properties of activated charcoal demonstrated the effect of charcoal on various chemical substances in aqueous solutions (Andersen, 1946), the effect of pH on charcoal adsorption properties (Andersen, 1947), and the effect of activated charcoal on the adsorption of strychnine from gastric contents (Andersen, 1948).

During the last two to three decades, there has been an increasing use of oral charcoal as a therapeutic intervention for oral poisoning. For many years, orally administered activated charcoal has been routinely incorporated into the initial treatment of a patient poisoned by the oral route. The term "activated" refers to the substantially increased adsorptive capacity that results from the processing of charcoal obtained from the burning of carbonaceous substances such as wood pulp, sugars, organic material, and industrial wastes. The processing involves extensive treatment with steam, carbon dioxide, oxygen, zinc chloride, sulfuric acid, or phosphoric acid at temperatures of 500°F to 900°F to "activate" the residue oxidation, which leads to a significant increase in surface area through creation of small pores in the material. Many organic molecules are significantly bound to activated charcoal. Generally, low-molecular-weight and polar compounds such as ethanol tend to be less well bound to activated charcoal. Substances such as lithium, iron, and certain inorganic salts are also not appreciably bound.

In acute oral overdose, activated charcoal is typically administered at a dosage of 1.0 to 1.5 g/kg. When the patient is unable to safely drink, the charcoal is placed into the stomach via an orogastric or nasogastric tube. Proper use of activated charcoal to prevent the absorption of orally administered toxicants requires that the patient's gag reflex be intact and expected to remain so in order to minimize the risk for aspiration of the administered charcoal. Once a recommendation to use a single dose of activated charcoal routinely for oral poisonings, now many are more cautious regarding the use of this moiety for decontamination (Chyka et al., 2005). The main reason cited for the reluctance is lack of definitive evidence of improvement in patient clinical outcomes. Given the obvious limitations to conduct adequately statistically powered, randomized, controlled clinical trials, many toxicologists are more inclined to utilize this method for potentially serious ingestions with appropriate clinical caution (Juurlink, 2016).

The incorporation of the procedure of whole bowel irrigation for the treatment of the poisoned patient has gained acceptance in specific poisoning situations. Whole bowel irrigation is a procedure that cleanses the lumen of the gastrointestinal tract. The procedure is accomplished with a poorly absorbed, osmotically neutral polyethylene glycol electrolyte solution that is administered orally to expel the contents of the intestines via the rectal route. This procedure is similar to that used to prepare a patient for endoscopic medical procedures of the large intestine. A unique use of this procedure in the setting of poisoning is for removal of ingested packets of illegal drugs swallowed by people smuggling the material and hoping to avoid detection by concealing the drugs in their intestines. Sometimes, the containers carried by body packers may leak and begin to cause symptoms that often lead the carrier to detection and treatment. Additional uses for this gastrointestinal decontamination technique are to prevent the ongoing absorption of sustained release formulations of drugs and for the early treatment of ingestions of substantial amounts of iron preparations or other orally ingested metallic poisons (Tenebein et al., 2004).

In summary, many clinical toxicologists agree that, for the prevention of further absorption following oral ingestion of most chemicals, the administration of oral activated charcoal provides an opportunity to lessen the systemic exposure of orally ingested toxicants that are likely to bind to charcoal, and if given in a timely fashion with appropriate clinical airway precautions. The other modalities described above have either a more limited role (whole bowel irrigation and gastric lavage) or a very rare place in gastric decontamination (syrup of ipecac) for use in the treatment of a poisoned patient. Most poison treatment centers favor the use of activated charcoal without lavage for treatment of oral poisoning and drug overdose. Many PCCs recommend home use of activated charcoal for immediate treatment of potentially significant poisonings. The use of ipecac syrup is largely limited to individual patients in whom it is likely to make a difference in outcome, such as the patients in rural environments, hours away from more definitive medical treatment, in whom it appears to be the most effective method available in that particular set of circumstances, or in whom it is the only method available to attempt gastric emptying.

Enhancement of Poison Elimination

There are several methods available to enhance the elimination of specific poisons or drugs once they have been absorbed into the systemic circulation. The primary methods employed for this use today include alkalinization of the urine, hemodialysis, hemoperfusion, hemofiltration, plasma exchange or exchange transfusion, and the administration of oral activated charcoal serially during the treatment time course.

The use of urinary alkalinization results in the enhancement of the renal clearance of certain weak acids. The basic principle applied is to increase urinary filtrate pH to a level sufficient to ionize the weak acid and prevent renal tubule reabsorption of the molecule. This is also referred to as ion trapping. The ion-trapping phenomenon occurs when the pK_a of the chemical is such that after the chemical undergoes glomerular filtration into the renal tubules, alteration of the pH of the urinary filtrate can ionize and "trap" the chemical in the urinary filtrate, lessening the extent to which it is reabsorbed. This increases the amount of toxicant that is eliminated in the urine per unit time, which is an indicator of the renal clearance of the toxicant. A schematic representation of this is shown for salicylate in Fig. 33-2.

Clinical use of this alkalinization procedure requires adequate urine flow and close clinical monitoring including that of the pH of the urine. The procedure is accomplished by adding sterile sodium bicarbonate to sterile water with 5% dextrose for intravenous (IV) infusion and administering the mixture intravenously to titrate the urine pH to 7.5 to 8.5. The drugs for which this procedure has been shown clinically efficacious include salicylate compounds and phenobarbital that have pK_as of 3.2 and 7.4, respectively. The increase in total body clearance for salicylate, for example, by increasing urinary pH from 5.0 to 8.0 can be substantial. The AAPCC and the European Association of Poisons Centres and Clinical Toxicologists 2004 Position Paper on Urinary Alkalinization recommend this procedure for moderately severe salicylate poisoning for a patient not meeting criteria for hemodialysis (Proudfoot et al., 2004).

Theoretically, there could be similar advantages to be gained from acidification of the urine regarding enhancement of clearance of drugs such as amphetamine and phencyclidine; however, there are significant adverse events associated with acidification such as acute renal failure and acidosis and electrolyte disturbances. For this reason, acidification of the urine is not recommended as a therapeutic intervention in the treatment of poisoning.

The dialysis techniques, either hemodialysis, continuous venous filtration, or peritoneal dialysis, rely on passage of the

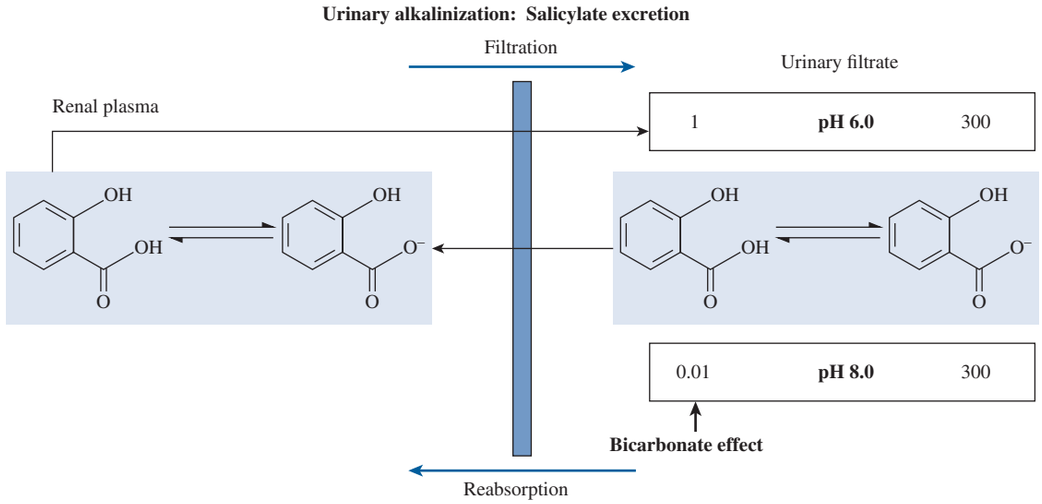

Figure 33-2. *Ion-trapping schematic for salicylate in the renal tubule.*

toxic chemical through a semipermeable dialysis membrane (or the patient's peritoneal membrane for peritoneal dialysis) so that it can equilibrate with the dialysate and subsequently be removed. Hemodialysis incorporates a blood pump to pass blood in close proximity to a dialysis membrane to allow chemicals permeable to the membrane to pass through and reach equilibrium. In order for this method to be clinically beneficial, the chemical must have a relatively low volume of distribution, low protein binding, a relatively high degree of water solubility, and low molecular weight. Use of hemodialysis to attempt to remove a chemical with the latter three characteristics but with a high volume of distribution, such as digoxin, would not be clinically beneficial, because the vast majority of the drug is not in the physiological compartment (blood) accessible to the dialysis membrane. Therefore, despite hemodialysis being able to effectively clear the digoxin in plasma during the dialysis run, most of the body burden of digoxin is located outside of the blood compartment and is not appreciably affected by the procedure. Similarly, if a drug is highly protein-bound, only a small percentage (the free fraction of the circulating toxicant) would be available to pass through the dialysis membrane and be cleared from the body. Some drugs, such as phenobarbital, can readily cross these membranes and go from a high concentration in plasma to a lower concentration in the dialysate. Phenobarbital has a relatively low volume of distribution (0.5 to 0.7 L/kg) and protein binding is also relatively low (30% to 50%), so the characteristics of the drug and its pharmacokinetic properties create appropriate conditions for the drug to be removed from the total body burden to make the technique valuable in serious cases of overdose (Brown et al., 1985; Cutler et al., 1987). Drugs and other chemicals for which hemodialysis has been shown to be clinically effective in the treatment of poisoning by these agents is shown in Table 33-6.

The technique of hemoperfusion is similar to hemodialysis except that there is no dialysis membrane or dialysate involved in the procedure. The patient's blood is pumped through a perfusion cartridge where it is in direct contact with adsorptive material (usually activated charcoal) that has a coating of material such as cellulose or a heparin-containing gel to prevent the adsorptive material from being carried back to the patient's circulation. The principle characteristics for a drug or other chemical to be successfully removed by this technique are low volume of distribution and adsorption by activated charcoal. This method can be used successfully with lipid-soluble compounds and with higher-molecular-weight compounds than for hemodialysis. Protein binding does not significantly interfere with removal by hemoperfusion. Because of the more direct contact of the patient's blood with the adsorptive material, the medical risks of this procedure include thrombocytopenia, hypocalcemia, and leukopenia. This technique is primarily used for the treatment of serious toxic exposures to theophylline, colchicine, paraquat, meprobamate, and possibly amanita phalloides toxin exposure. The technique is not often employed and, perhaps for this reason, not all healthcare facilities actively stock the specialized, sterile hemoperfusion cartridge required for the procedure. This limitation results in the procedure usually only available at major, metropolitan treatment centers.

The use of the technique of hemofiltration for the treatment of poisoning has been suggested as an additional modality for enhancement of chemical elimination. During this procedure, the patient's blood is delivered through hollow fiber tubes and an ultrafiltrate of plasma is removed by hydrostatic pressure from the blood side of the membrane. Different membrane pore sizes are available for use so the size of the filtered molecules can be controlled during the

Table 33-6

Chemicals for Which Hemodialysis Has Been Shown Effective as a Treatment Modality for Poisoning

Alcohols	Lithium
Antibiotics	Meprobamate
Boric acid	Metformin
Bromide	Methotrexate
Caffeine	Paraldehyde
Calcium	Phenobarbital
Chloral hydrate	Potassium
Carbamazepine	Salicylates
Diethylene glycol	Strychnine
Fluorides	Theophylline
Iodides	Thiocynates
Isoniazid	Valproic acid
Isopropanol	

procedure. The perfusion pressure for the technique is either generated by the patient's blood pressure (for arteriovenous hemofiltration) or by a blood pump (for venovenous hemofiltration). Needed fluid and electrolytes removed in the ultrafiltrate are replaced intravenously with sterile solutions. The procedure has the advantage of running continuously as opposed to the 4- to 6-hour limitation for a hemodialysis treatment cycle. One potential advantage of continuous filtration versus intermittent hemodialysis is that the rebound phenomenon does not occur with continuous filtration. Rebound phenomenon is the observed sharp increase in plasma toxicant concentration shortly after hemodialysis is terminated due to redistribution of the toxicant from the nonvascular, tissue, compartment to the vascular space. This rebound is commonly seen during hemodialysis for lithium overdose (Bosinski et al., 1998). Thus far, clinical evidence to support continuous filtration for enhancing total body clearance of toxicants in poisoning cases is insufficient to encourage wide usage of the procedure (Goodman and Goldfarb, 2006).

The use of either plasma exchange or exchange transfusions has been relatively limited in the field of clinical toxicology. Although the techniques afford the potential advantage of being able to remove high-molecular-weight and/or plasma protein–bound toxicants, the clinical utility in poison treatment has been limited. Plasma exchange or plasma pheresis involves removal of plasma and replacement with frozen donor plasma, albumin, or both with IV fluid. The risks and complications of this technique include allergic-type reactions, infectious complications, and hypotension (Mokrzycki and Kaplan, 1994). Exchange transfusion involves replacement of a patient's blood volume with donor blood. The use of this technique in poison treatment is relatively uncommon and mostly confined to the setting of inadvertent drug overdose in a neonate or premature infant in the setting of a neonatal intensive care unit.

Serial oral administration of activated charcoal, also referred to as multiple-dose activated charcoal (MDAC), has been shown to increase the systemic clearance of various drug substances. The mechanism for the observed increase in total body clearance associated with the use of repeated doses of oral charcoal is thought to be translumenal efflux of drug from blood to the charcoal passing through the gastrointestinal tract (Berg et al., 1982). In addition, MDAC is thought to produce a further enhancement in clearance by interrupting the enteroenteric–enterohepatic circulation of drugs that undergo that pharmacological route of elimination and recirculation. After systemic absorption, a drug may reenter the gut lumen by passive diffusion if the intraluminal drug concentration is lower than that in blood. The rate of this passive diffusion depends on the concentration gradient and the intestinal surface area, permeability, and blood flow. The activated charcoal in the gut lumen serves as a "sink" for toxicants. A concentration gradient is maintained and the chemical passes continuously into the gut lumen, where it is adsorbed to charcoal. The characteristics of chemicals that favor enhanced elimination by MDAC include (1) significant enteroenteric–enterohepatic circulation, including the formation of active recirculating metabolites, (2) prolonged plasma half-life after an overdose, (3) small (<1.0 L/kg) volume of distribution, (4) limited (<60%) plasma protein binding, (5) a pK_a that maximizes transport of the drug across cell membranes, (6) sustained-release/resin-form tablets and/or capsules, and (7) onset of organ failure (e.g., kidney) that results in reduced capacity of the major route of elimination of the toxicant (for renally excreted chemicals) so that MDAC may make a considerable contribution to total body clearance.

The technique involves continuing oral administration of activated charcoal beyond the initial dosage (described above) every 2 to 4 hours with approximately one-half the initial dose, or 0.5 g/kg.

Table 33-7

Drugs for Which Multiple Dose Activated Charcoal Has Been Shown Effective as a Treatment Modality for Poisoning

Carbamazepine	Nadolol
Dapsone	Phenobarbital
Digoxin	Salicylates
Digitoxin	Theophylline

The charcoal is generally mixed as an aqueous slurry and a cathartic substance is not incorporated due to the potential for electrolyte abnormalities with repeated administration of cathartic agents. An alternative technique for MDAC is to give the activated charcoal via an orogastric tube or nasogastric tube a loading dose of 1.0 g/kg of an aqueous slurry of activated charcoal, followed by a continuous infusion intragastrically of 0.2 g/kg/h. The duration of gastric infusion depends on the clinical status of the patient and repeated monitoring of plasma drug concentrations where indicated (Pollack et al., 1981; Van de Graaff et al., 1982; Park et al., 1983, 1986; Mofenson et al., 1985; Ohning et al., 1986; Ilkhanipour et al., 1992; Goulbourne et al., 1994; Chyka, 1995; Weisman, 1998).

Studies in animals and human volunteers have shown that MDAC increases drug elimination significantly, but few prospective randomized controlled clinical studies in poisoned patients have been published, demonstrating a significant reduction in patient morbidity or mortality when MDAC is employed. One study, however, does provide a striking example of clinical benefit from the use of MDAC (de Silva et al., 2003). The study showed that patients who intentionally poisoned themselves with yellow oleander seeds (a cardiac poison) and were randomized to MDAC (after all patients received an adequate initial single dose of activated charcoal) had a statistically improved outcome in both mortality and cardiac morbidity. The early use of MDAC is an attractive alternative to more complex methods of enhancing toxicant elimination, such as hemodialysis and hemoperfusion, although only in a relatively small subset of patients. The decision to use MDAC depends on the clinical situation, including the specific chemical involved, the presence of contraindications (e.g., intestinal obstruction) to the use of MDAC, and the likely effectiveness of alternative methods of therapy. A list of chemicals for which MDAC has been shown as an effective means of enhanced body clearance is provided in Table 33-7.

Use of Antidotes in Poisoning

A relatively small number of specific antidotes are available for clinical use in the treatment of poisoning. There are several reasons for the overall paucity of available specific antidotes for poisonings. The two primary reasons are the practical difficulties in performing clinical research in poisoned patients, and the relatively small financial incentives for commercial development of poisoning antidotes. Shortly after the terrorist attack on the United States in 2001, the federal government put in place an FDA authorization to stimulate innovative development of therapeutic agents to treat chemical, biologic, and radioactive attacks. In 2002, the FDA enacted the Animal Efficacy Rule (Animal Rule), a regulation that allows sponsors to attain FDA approval of some products based on safety testing in humans and efficacy testing only in animals (Gaffney, 2015). This rule is intended to allow FDA to approve products intended to treat serious or life-threatening conditions caused by exposure to lethal or permanently disabling toxic biological, chemical, radiological, or

nuclear substances for the indications of treatment of chemical, biologic, or radiologic mass poisonings, such as could be expected in a terrorist attack. For obvious reasons, testing of therapeutic agents for efficacy would not be possible for ethical and/or logistical reasons. The Animal Rule allows the sponsor to establish product efficacy in a validated animal model and then provide preapproval human safety data, in healthy human volunteers. The human safety data would involve administration of therapeutic dosages of the chem/bio/rad treatment agent in the absence of the poisoning. The pharmaceutical company-sponsor would also be expected to perform a field study post-approval, in the event that the indicated exposure occurs naturally for infectious outbreaks or during an attack.

In addition to the Animal Rule Act, the FDA has in place, since 1983, the Orphan Drug Act that provides financial incentives to companies who develop therapies for treatment of rare diseases, defined as affecting less than 200,000 persons in the United States (Orphan Drug Act, 2013). Several treatments for poisoning have been approved under the orphan regulations. Fomepizole (4-methylpyrazole), a chemical inhibitor of alcohol dehydrogenase, was approved as an antidote for ethylene glycol (and later methanol) poisoning via the Orphan Drug pathway in December 1997. Two chelating agents, insoluble Prussian blue and Pentetate Calcium Trisodium, were approved in 2003 and 2004, respectively, for the treatment of exposure to radioactive heavy metals. Another Orphan Drug Act approval was hydroxocobalamin, a cyanide chelating agent. This chemical was approved in the United States in December 2006 after being approved in Europe many years earlier. Despite these early successes, there have not been a large number of antidote products approved to this point in time as a result of this regulatory incentive.

The mechanism of action of various antidotes is quite different. For example, a chelating agent for heavy metal poisoning or Fab fragments specific to digoxin or crotalid venom work by physically binding the toxicant, preventing the chemical from exerting a deleterious effect in vivo and, in some cases, facilitating body clearance of the chemical. In essence, the Fab fragments serve as biologically derived chelating agents to bind and render the specific chemical inactive. Other antidotes pharmacologically antagonize the effects of the toxicant at the endogenous receptor level. Such is the case with atropine, an antimuscarinic, anticholinergic drug used to pharmacologically antagonize at the receptor level, the effects of organophosphate insecticides or acetylcholinesterase-inhibiting nerve gases, which produce cholinergic, muscarinic effects, which if sufficient, can be lethal. Certain chemicals exert their antidote effects by chemically reacting with biological systems to increase the detoxifying capacity for the toxicant. For example, sodium nitrite is given to patients poisoned with cyanide to cause formation of methemoglobin, which serves as an alternative binding site for the cyanide ion, thereby making it less toxic to vital body systems. Other chemicals, such as L-carnitine, are available to mitigate the biochemical toxicity of high exposures to valproic acid (an antiseizure medication) at the level of the mitochondria. Just as in other therapeutic areas of drug development, basic research into fundamental mechanisms can reveal viable drug targets that can be exploited to produce a point of intervention for a drug/antidote to lessen the effects of a toxic exposure.

An example of an efficacious antidote with an uncertain mechanism is intravenous lipid emulsion (ILE) therapy. ILE as a product has been in clinical use for decades as a nutritional supplement for seriously ill patients who were not able to receive nutrition via their gastrointestinal tract. As an antidote, the 20% lipid emulsion solution is most often employed. The discovery of the beneficial effects of ILE comes from the anesthesiology community, through initial basic science work and then experimental clinical use in potentially fatal human accidental exposures. Briefly, the use of regional nerve block local anesthesia has been longstanding. A significant and potentially fatal adverse consequence of this procedure was inadvertent IV injection of a local anesthetic (LA) drug that results in high, likely cardiotoxic concentrations of the LA in the systemic circulation. There were no effective treatments readily available to prevent this toxicity once the misdirected injection had occurred. Because LA drugs are generally highly lipophilic, the anesthesiologists experimented with the immediate use of ILE in animal models and found a beneficial effect on survival (Weinberg et al., 1998). Subsequently, beneficial effects in patients having nerve block procedures, who experienced inadvertent IV administration of the anesthetic drugs, were published as case reports (Rosenblatt et al., 2006).

The current understanding of the mechanism of action is that the ILE serves as a lipid sink in the blood compartment, partitioning the LA predominantly into the lipid phase in blood (ILE), reducing the relative concentration of the cardiotoxic LA in the aqueous phase of the blood. This partitioning then decreases the fraction of the LA that is then available to penetrate target organ tissue and exert a deleterious effect. Other mechanisms proposed as either primary or contributory to the beneficial effect of ILE on LA toxicity include enhancement of cardiac metabolism, that is, fatty acids from the ILE provide an energy source to cardiac myocytes; another possible mechanism is that ILE activates cardiac Ca and Na channels. While there is some evidence to support the energy enhancement and ion channel mechanisms, the partitioning mechanism at this point in time is more strongly supported.

The use of ILE therapy is recommended for treatment of significant systemic toxicity of LAs, including cardiac arrest from inadvertent IV administration of the LA. ILE use for the treatment of non-LA poisoning by lipophilic toxicants is not well supported by evidence (Cao et al., 2015; Levine et al., 2016). Despite the lack of evidence to support the use of ILE non-LA poisonings, many clinical toxicologists will recommend a therapeutic trial of this treatment in the setting of serious cardiovascular effects from lipophilic toxicants such as a calcium channel blocker or beta-blocker not responsive to first or second line treatments. More research is needed to fully understand the optimum use of ILE outside of intravenous poisoning with LA agents.

The time course for antidote onset of action is highly variable across currently available antidotes. Naloxone, given intravenously (IV), can have a dramatic effect on the level of consciousness of an opiate-poisoned patient within minutes of administration. Chelating agents such as desferoxamine may require multiple dosages over many days before a clinically detectable effect is seen.

The skillful therapeutic use of antidotes is essential to optimize the treatment of the poisoned patient. Many antidotes have a relatively narrow safety margin or low therapeutic index. Excessive dosing with an antidote can in some instances be more harmful than the expected effects of the toxicant itself. An example of this is when physostigmine (a cholinergic agent) is given at an excessive dose or dosing rate to a patient with mild-to-moderate anticholinergic poisoning, the antidote can cause a potentially fatal bradycardia that can progress to a fatal cardiac arrest. Some antidotes require an adjustment of their dosage based on a measured blood concentration of the chemical (e.g., digoxin Fab fragments), or based on the clinical assessment of the patient such as with sodium bicarbonate usage in a tricyclic antidepressant overdose. A significant part of the clinical training in the field of medical toxicology is devoted to learning how to use antidotes skillfully.

An important area of research in clinical toxicology has been in the study of prognostic indicators of poisoning severity and predictors for the level of treatment required. For practical reasons

much of this work has been retrospective in nature but has resulted in significant aids to guide the treatment rendered by clinical toxicologists. Several authors have proposed "action levels" that are a threshold for a certain level of clinical intervention based upon a measured plasma concentration of the chemical or a clinical manifestation of the poisoning. One of the best examples of a quantitative relationship between plasma concentrations and prognostic stratification is the previously mentioned nomogram used for acetaminophen concentration and risk of hepatotoxicity (Rumack et al., 1981). As discussed below as a case example, this retrospective analysis of 662 patients with excess acetaminophen exposure was the basis of a nomogram to aid in the risk stratification for significant hepatic toxicity that is still in use today. Similarly, a patient with a measured plasma valproic acid concentration of 900 mcg/mL after a single oral exposure would be expected to exhibit significant toxicity. If the patient's clinical condition correlated with the measured laboratory plasma concentration (i.e., laboratory error was unlikely), the patient would likely require aggressive treatment measures such as hemodialysis instead of only supportive care. Use of a patient-derived prognostic indicator that correlates with clinical outcome can also involve electrocardiographic measurements. An example of this is the case series study considering the publication that described the relationship of the QRS interval on the patient's 12-lead electrocardiogram (ECG) and the severity of poisoning by tricyclic antidepressant drugs (Boehnert and Lovejoy, 1985). This important observational study helped to stratify patients poisoned with an overdose of first-generation tricyclic antidepressants into risk categories based on the drug-induced, lengthening of the QRS on the patient's ECG to predict the eventual development of seizures or cardiac arrhythmias in the course of the poisoning. This, like the Rumack–Matthew nomogram for acetaminophen, is still clinically useful more than 30 years after publication.

Another way that prognostic information is studied is when a constellation of clinical signs and symptoms is proven to correlate with a clinical outcome following exposure to a specific poison. An example of this would be a worker with a significant topical methanol exposure who demonstrates a metabolic acidosis with an elevated AG, an osmol gap, and visual symptoms. Based on clinical signs and symptoms, this patient would likely undergo hemodialysis even in the absence of a confirmatory measurement of the methanol concentration in serum. These relationships, the correlation of serious clinical effects with a valproic acid level above 900 mcg/mL or visual symptoms in a methanol-poisoned patient (Ellenhorn, 1997a, 1997b), have been derived from many years of observational study of poisoning outcomes by investigators in the field of clinical toxicology.

Early on in clinical toxicology, the majority of publications were primarily case reports making it difficult to determine the relative effectiveness of various treatments being assessed. There were also significant discrepancies in the initial management of the patients confounding the ultimate outcomes of the cases. The case series or meta-analysis type of scientific analysis was a helpful step to advance the study of clinical outcomes and assess the quality of treatment provided to poisoned patients. The highest level of evidence for establishing efficacy and safety for therapeutic interventions is the prospective, double blinded, controlled, clinical trial. Whenever possible to successfully execute, these clinical investigations are most likely to result in objective data with the least confounding of results if properly conducted. These advantages better enable clinicians to validate (or dismiss) new therapeutic modalities and treatment strategies. Unfortunately, the ability to perform these trials in the evaluation of new treatments for poisoning is significantly limited due to ethical concerns when considering withholding effective treatment (placebo treatment), or the ability to effectively blind treatment groups in the poison treatment setting. In addition, the heterogeneity between individual poisoning cases would likely introduce potential unbalanced, confounding factors into the study that could lead to inaccurate results.

Supportive Care of the Poisoned Patient

Once the initial treatment phase in the clinical management of the poisoned patient has been successfully completed, the care of the patient is generally shifted to an inpatient hospital setting for those patients who will require admission. This supportive care phase of poison treatment is very important. Poisoned patients who are unstable or at risk for significant clinical instability during the later phases of their poisoning are generally admitted to a critical care unit for close monitoring. In addition, patients who are excessively sedated from their poisoning or those who require mechanical ventilation or invasive hemodynamic monitoring are also candidates for an intensive care stay. Not only are there certain poisonings that have delayed toxicity such as acetaminophen, paraquat, and diphenoxylate, but there are also toxicants that exhibit multiple phases of toxicity that include delayed effects (i.e., ethylene glycol, salicylate, and buspirone).

Similar to other seriously ill, hospitalized patients, patients admitted for continued treatment of poisoning are at risk for nosocomial infections, iatrogenic fluid and electrolyte disturbances, as well as potential harmful effects from the initial therapies that they received for treatment of their poisoning. For example, gastric lavage, or orogastric infusion of activated charcoal can cause aspiration and lead to pneumonitis. Any drug that severely alters a patient's mental status causing obtundation can allow aspiration of gastric contents associated with a loss of the gag reflex. Organ system dysfunction due to profound hypotension caused by a poisoning can result in delayed complications such as acute renal failure, hepatic failure, and permanent brain damage. Close clinical monitoring can detect later phase poisoning complications and allow an opportunity for prompt medical intervention to minimize patient morbidity and mortality. These are but a few of the reasons that close vigilance is a very important component of the support phase of poison treatment.

Another important component of the supportive care phase of poison treatment is the psychiatric assessment. For intentional self-poisonings, a formal psychiatric evaluation of the patient should be performed prior to patient discharge. In many cases, it is not possible to perform a psychiatric interview of the patient during the early phases of treatment and evaluation. Once the patient has been stabilized and is able to effectively communicate, the psychiatric evaluation should be obtained prior to determining the patient's disposition. Generally, a patient who has attempted suicide should be constantly observed until they have been evaluated by the psychiatric consultant and judged to be at low risk for being without constant surveillance.

CASE EXAMPLES OF SPECIFIC POISONINGS

Acetaminophen

A 16-year-old female patient arrives in the ED by ambulance after being found by a parent in what appeared to be an intoxicated state with empty pill bottles scattered about her room. The parent reports the patient was despondent recently after breaking up with her boyfriend. The patient is tearful and reports abdominal pain and admits to drinking alcohol and taking over-the-counter (OTC) pills in an apparent suicide attempt. The estimated time of ingestion is 6 hours prior to arrival in the ED. The patient does not use prescriptions, OTC medications, or dietary supplements on a regular basis and

is not known to have a history of regular consumption of alcoholic beverages or use illicit drugs. In addition, the patient did not have a history of psychiatric disorders or previous suicide attempt.

On physical examination the vital signs were blood pressure 118/80 mm Hg, pulse 88/min and regular, respiratory rate 18/min, and temperature 37.0°C. She was awake and oriented to person, place and time, responded to questions appropriately with slightly slurred speech. Other pertinent findings included normal bowel sounds with mild epigastric tenderness. The neurological examination was only significant for slightly slurred speech.

Routine clinical laboratory studies were ordered STAT (electrolytes, creatinine, BUN, glucose, complete blood count with differential, coagulation studies, urine analysis, and urine toxicology screen) an ethanol level, salicylate level and a plasma acetaminophen level. Chest and abdominal radiography were normal.

The patient was given 1.5 g/kg oral activated charcoal as a slurry in a sorbitol cathartic and placed in the intensive monitoring section of the ED while the laboratory tests were being performed. Forty minutes later, the laboratory results returned and showed a mildly increased white blood cell count, liver transaminase values were elevated at approximately three times the upper limit of normal, and an acetaminophen concentration was 308 μg/mL. Salicylate was not detected; ethanol level was 89 mg/dL (just above the legal threshold for driving while intoxicated in most states). She denied taking any other medications with the acetaminophen and alcohol. Based on the Rumack–Matthew nomogram (Fig. 33-1), a plasma acetaminophen concentration of 308 μg/mL at approximately 6 hours after ingestion is well within the "probable hepatic toxicity" range, and therefore treatment with *N*-acetylcysteine (NAC) was required.

The patient received the first dose of IV NAC in the ED and was admitted to the medical ward to complete the treatment course of IV NAC. Hepatic transaminases remained elevated over the ensuing 2 days of the hospitalization, peaking at five times the upper limit of normal. The patient's bilirubin remained within the normal range as did indices of synthetic hepatic function (coagulation pathway measurements). The patient was seen by the Psychiatry Consultation service, which determined she was not actively suicidal; she was discharged from the hospital 2 days after admission with scheduled psychiatric and medical follow-up appointments.

Acetaminophen has been used as an analgesic and antipyretic since the mid-1950s and has become more prominently recognized as a potential hepatotoxicant in the overdose situation since the original British reports in the late 1960s (Proudfoot and Wright, 1970). Work on the mechanisms of the liver toxicity of this drug has provided a scientific basis for therapy (Mitchell et al., 1973).

The clinical presentation of patients poisoned with acetaminophen is sufficiently confusing in some cases; it is difficult to estimate the time of ingestion. Due to the paucity of clinical symptoms with acute overdose, waiting for the appearance of symptoms is an inadequate strategy for the clinical decision-making process regarding institution of treatment. Most clinicians will request an acetaminophen concentration be measured for any patient suspected of having a toxic exposure to any substance precisely for the reason highlighted above—that is the paucity of signs and symptoms associated with an acetaminophen overdose makes inadvertent missing of a potentially fatal overdose until the window for maximum antidote effectiveness has passed.

Acetaminophen in normal individuals is inactivated by sulfation (approximately 52%) and glucuronide conjugation (42%). About 2% of the drug is excreted unchanged. The remaining 4% is biotransformed by the cytochrome P-450 mixed-function oxidase system. The P-450 isozyme responsible for acetaminophen biotransformation is CYP2E1. Metabolism by CYP2E1 results in a potentially toxic metabolite that is normally detoxified by conjugation with glutathione and excreted as the mercapturate. Evidence extrapolated from animal studies estimates that when 70% of endogenous hepatic glutathione is consumed, the toxic metabolite becomes available for covalent binding to hepatic cellular components. However, patients who are concurrently using, or have recently used, chemicals that induce CYP2E1, such as in the case of chronic ethanol exposure or phenobarbital use, may produce more than 4% of the toxic metabolite. It is therefore important to determine, whenever possible, whether or not the patient's CYP2E1 system may be induced when assessing the risk of hepatic necrosis from acetaminophen overdose in any given individual. When there is evidence (medical history) of concurrent chemicals that induce CYP2E1, the treatment nomogram for acetaminophen does not directly apply, and interpretation by the treating physician must be modified to a lower threshold for treatment with NAC (Rumack et al., 1981).

Follow-up liver biopsy studies of patients who have recovered 3 months to a year after hepatotoxicity have demonstrated no long-term sequelae or chronic toxicity (Clark et al., 1973). A very small percentage (0.25%) of patients in the national multi-clinic study conducted in Denver may progress to hepatic encephalopathy with subsequent death. The clinical nature of the acetaminophen overdose is one of sharp peaks of serum glutamic-oxaloacetic transaminase (SGOT) by day 3, with recovery to less than 100 IU/L by day 7 or 8. Patients with SGOT levels as high as 20,000 IU/L have shown complete recovery and no sequelae 1 week after ingestion (Arena et al., 1978).

Laboratory evaluation of a potentially poisoned patient is crucial in terms of both hepatic measures of toxicity and plasma levels of acetaminophen. Accurate estimation of acetaminophen in the plasma should be done on samples drawn at least 4 hours after ingestion, when peak plasma concentrations are expected.

Once an accurate plasma level has been obtained, it should be plotted on the Rumack–Matthew nomogram to determine whether NAC therapy is indicated (Fig. 33-1). This nomogram is based on a series of patients with and without hepatotoxicity and their corresponding measured plasma acetaminophen concentrations.

Treatment should be instituted in any patient with a plasma concentration in the potentially toxic range. Some clinical toxicologists recommend withholding NAC treatment unless the plasma concentration is at or above the "probably toxic" demarcation, but most often, due to the inherent uncertainty in the history regarding the time of ingestion (the *x*-axis of the Rumack nomogram), the more conservative approach is recommended. Standard gastric decontamination measures with administration of activated charcoal in the case of a relatively recent oral ingestion should accompany the administration of IV NAC. The protective effect of NAC in oral acetaminophen poisoning was demonstrated when contrasted with controls not receiving antidotal therapy (Rumack et al., 1981; Smilkstein et al., 1988). Because NAC is most effective if it is given within 8 to 12 hours of acetaminophen ingestion, patients in whom blood levels cannot be obtained quickly should have NAC treatment instituted and therapy terminated only if levels are nontoxic. The dosing regimen for oral NAC is a loading dose of 140 mg/kg orally, followed by 70 mg/kg orally for 17 additional doses (Peterson and Rumack, 1977). The dosage regimen for IV NAC is 150 mg/kg loading dose over 15 minutes, followed by 50 mg/kg over the next 4 hours then 100 mg/kg over 16 hours for a total dose of 300 mg/kg in 20 hours. Anaphylactoid reactions have been associated with the use of IV NAC; therefore, some authors do not recommend this route of administration for adults with asthma. Children can receive IV NAC but the volume required for the dilution can cause electrolyte abnormalities.

The advantage from using the IV form is that the complete dosage regimen is completed in 20 hours in contrast to the 72-hour oral regimen. Children less than 9 to 12 years of age have a lower incidence of hepatotoxicity after an overdose than do adults, but are still treated with NAC according to the Rumack–Matthew nomogram. Patients with trivial or "nontoxic" acetaminophen ingestions should not be given NAC therapy because the antidote can produce clinical side effects.

Ethylene Glycol

A 37-year-old female was brought to the ED after being found unresponsive in her home. The patient was comatose and unresponsive to pain and without obvious signs of trauma. At the scene, emergency medical personnel administered oxygen and naloxone and performed a finger stick for glucose (standard procedure for encountering a person with altered mental status and suspected toxic ingestion), which showed a normal value of 95 mg/dL. The patient's spouse reported that she had been depressed and despondent with the recent loss of her job. No empty pill bottles or liquid containers were found with her at home.

Upon arrival to the hospital, she remained comatose and had the following vital signs: blood pressure 105/65 mm Hg, pulse 78/min, respiratory rate elevated at 32/min, and her body temperature was normal. The remainder of the physical examination was significant as her pupils were 3 mm and sluggishly reactive to light; the lung and heart examinations were normal; the abdominal examination revealed diminished but present bowel sounds, no tenderness, organomegaly, or masses were detected. The rectal examination was normal; the stool was without detectable gross or occult blood. Neuro examination was nonfocal with a diminished gag reflex.

The patient was placed on a cardiac monitor, an IV line was started, clinical laboratory specimens were obtained, and she was placed on oxygen, given naloxone, thiamine, and one dose of dextrose (50%) intravenously. Similar to the EMSs, these treatments are standard for patients presenting with an altered mental status to an ED. Chest and abdominal radiography was without abnormality. A 12-lead ECG was also normal. Faced with the uncertainty of oral ingestion versus topical and inhalation exposure, a decision was made to proceed with gastric decontamination. Because no direct history from the patient was available, a mixed ingestion could not be ruled out as well. Because of a diminished gag reflex, the patient was endotracheally intubated to protect her airway before an orogastric tube was placed. Gastric lavage was performed and no blood or pill fragments were found. The gastric lavage fluid withdrawn from the stomach was bright yellow in appearance and slightly viscous. When a Wood's lamp illuminated this fluid in a darkened room, fluorescence was observed. This finding suggests the presence of automotive antifreeze that contains ethylene glycol. Activated charcoal (2.0 g/kg) was placed via the orogastric tube into the stomach with a cathartic even though the efficacy for binding ethylene glycol is limited; the use of activated charcoal here was intended for other, potentially unknown coingestants. Clinical laboratory results returned showing the following:

Serum Chemistries

Na = 140 mEq/L	K = 3.1 mEq/L
Cl = 94 mEq/L	HCO_3 = 8 mEq/L
BUN = 12 mg/dL	Glucose = 100 mg/dL

Arterial blood gas:

pH = 7.20; pCO_2 = 20 mm Hg; pO_2 = 98 mm Hg

The complete blood count was normal, the urine analysis was normal, measured serum osmolarity was 330 mOsm/kg, and acetaminophen and salicylate levels were below the limits of detection, and the urine toxicology screen was negative.

The laboratory results were interpreted as follows: a metabolic acidosis with elevated AG (AG = 38; normal < 12) and an elevated osmol gap (40 mOsm; normal < 10 mOsm). These findings are consistent with either methanol or ethylene glycol poisoning (Tables 33-4 and 33-5). A blood sample for measurement of methanol and ethylene glycol was sent for analysis but based on the history and finding of fluorescent, yellow fluid in the stomach and the acid–base disorder detected, the working diagnosis of ethylene glycol poisoning was established. The patient was treated with IV fomepizole (4-methylpyrazole) and transfer to a nearby regional hospital that has hemodialysis capability was requested. Sodium bicarbonate was given intravenously for the profound metabolic acidosis and the patient was successfully transferred to the regional medical center where she underwent hemodialysis shortly after arrival. After 4 hours of hemodialysis, the acid–base and electrolyte abnormalities were corrected but the patient remained comatose. Approximately, 9 hours after the blood specimen was sent from the first hospital, the laboratory reported a "toxic" serum ethylene glycol concentration of 366 mg/dL, a likely fatal exposure to ethylene glycol. The patient underwent a second 4-hour course of hemodialysis 8 hours following the initial hemodialysis treatment to again correct a recurrence, although less severe, of her metabolic acidosis with the appearance of minor renal injury (serum creatinine increased to 1.8 mg/dL). She regained normal consciousness approximately 18 hours after arrival at the second hospital; her renal function recovered completely within 5 days. Subsequently, the patient admitted that she intentionally drank more than half a container of antifreeze with the intent of harming herself. She was evaluated by the psychiatry consultation service and transferred to their service for further care.

This case demonstrates the importance of utilizing the anion and osmol gap calculations in overdose patients as well as all available diagnostic tools (e.g., the Wood lamp) during the initial evaluation of a potentially poisoned patient. It also highlights the life-saving features of rapidly and competently applied therapeutic modalities in poisoning treatment. Without a readily available drug such as fomepizole (or sterile IV ethanol a substitute for fomepizole that also inhibits the alcohol dehydrogenase enzyme) and the ability to rapidly transfer to a facility with definitive care capability (hemodialysis), this patient would have likely succumbed to her poisoning. Initiation of antidote therapy early and providing hemodialysis to increase removal of the poison prior to receipt of the confirmatory laboratory test (measured serum concentration of the specific poison—ethylene glycol) was also required in this case. Although not considered diagnostic (Walker et al., 1986), the presence of both a metabolic acidosis with an AG and an osmol gap is highly suggestive of either methanol or ethylene glycol given the patient's presentation despite a scant history. It is commonplace for hospital clinical laboratories to have to "send out" blood specimens for ethylene glycol and methanol analysis as these are not routinely performed on-site. A turn-around time of 6 to 12 hours for this test result to be available is typical in most settings.

Ethylene glycol exerts its primary toxicity after undergoing biotransformation by alcohol dehydrogenase to glycolic acid and then to glyoxylic and oxalic acid by the action of aldehyde dehydrogenase. Fig. 33-3 contains a schematic representation of the metabolism of ethylene glycol to its toxic metabolites. The latter two acid metabolites are thought to be responsible for both the renal and the acid–base toxicity observed during poisoning by ethylene glycol (Swartz et al., 1981). If untreated or treated too late, ethylene glycol poisoning can

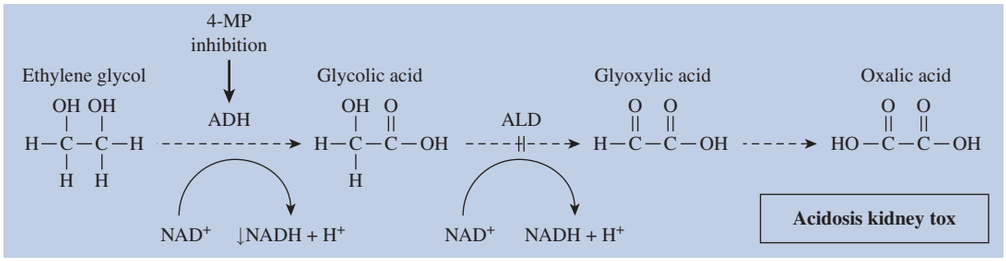

Figure 33-3. *Metabolic pathway for the metabolism of ethylene glycol.*

result in fatal cerebral edema with seizures as well as irreversible renal damage. Hemodialysis can remove the unmetabolized ethylene glycol and toxic, more polar metabolites, eliminating the substrate for production of these harmful metabolites and the damaging metabolites themselves. Administration of an inhibitor or competing substrate for alcohol dehydrogenase can be instituted before and during transport of the patient to a healthcare facility where hemodialysis is available. Fomepizole (4-methylperazole) is a commercially available inhibitor of alcohol dehydrogenase that is FDA approved for the treatment of methanol and ethylene glycol poisoning. Ethanol (sterile, for IV administration) or oral, nonsterile ethanol (when the IV formulation is not readily available) can also be given to effectively inhibit the metabolism of methanol or ethylene glycol and prevent the potentially devastating effects of the poisoning. Finally, in the specific case of methanol poisoning, the administration of folic acid in animal models has been shown to enhance the in vivo clearance of formate, the toxic metabolite of methanol (McMartin et al., 1977). Folate or folinic acid has been given to methanol-poisoned patients and is suggested to hasten formic acid metabolism, thereby accelerating its clearance (Noker et al., 1980). Many clinical toxicologists will include folic or folinic acid in their therapeutic regimen for methanol-poisoned patients. Poisoning with methanol or ethylene glycol is relatively common; several thousand cases per year are reported to the AAPCCs. A review of these cases has shown that even high exposures of either toxicant can be survivable, given early recognition of the poisoning and rapidly applied therapies (Kruse, 2012).

Valproic Acid

A 33-year-old male is brought to the ED after being found unresponsive by his brother at home with two empty prescription pill bottles of extended release valproic acid at his side. He was last seen 8 hours prior to being found unresponsive and was then in normal health. No further history is available. The patient's pharmacy confirmed that three monthly prescriptions, each containing 30, 250 mg extended release valproic acid tablets had been dispensed within the preceding 3 months. A call to the office of the prescribing physician did not reach anyone who could verify the prescription or provide past medical history for the patient.

The patient was unresponsive to verbal or tactile stimulation with vital signs: blood pressure 85/55 mm Hg, pulse 94/min, respiratory rate 20/min, and temperature 33.2°C. IV access was obtained and IV fluids were administered as rapidly as possible. Naloxone was administered without effect. The patient was placed on a cardiac monitor that showed sinus rhythm. The remainder of the physical examination showed the patient to be without obvious signs of trauma; the skin was cool and without track marks. The pupils were 2 mm and poorly reactive to light. Other significant findings included the examination of the abdomen, which showed diminished bowel sounds. The rectal examination was negative for occult blood. The neurological examination revealed coma without focal motor abnormalities and an absent gag reflex.

Initial clinical laboratory results showed mild metabolic acidosis with elevated serum lactate, an increased anion, slightly increased serum ammonia, normal glucose, liver function tests, and renal function tests. The chest and abdominal radiographs were normal. The 12-lead ECG showed a prolonged QT interval without arrhythmia. The patient was endotracheally intubated to protect his airway prior to gastric lavage that yielded some pill fragments only. The patient was placed on a ventilator to support his respiration. Activated charcoal (1.5 g/kg) was administered via the orogastric tube immediately following the lavage procedure. The blood pressure continued to remain low despite IV fluid administration. A STAT valproic acid serum measurement showed the concentration was 572 mcg/mL.

Blood pressure responded to low-dose vasopressors (IV dopamine) with continued IV fluid administration. A repeat serum valproic acid concentration was 890 mcg/mL at 2 hours post admission. Serial oral activated charcoal (every 4 hours) was initiated via the orogastric tube and hemodialysis was started 3 hours after admission. IV L-carnitine was given when a repeat serum ammonia concentration returned further elevated at 94 mg/dL. Subsequent measured plasma concentrations of vaproic acid gradually declined to <100 mcg/mL over the next 48 hours after one additional hemodialysis session was conducted. The patient regained consciousness 24 hours after admission and made a full recovery by hospital day 4. He was evaluated by the Psychiatry consult service, which accepted the patient in transfer to their inpatient service after he was medically cleared by the Toxicology service.

This case illustrates the significance of increasing plasma concentrations of the toxic substance despite gastric decontamination procedures. In this case, the most likely cause for this observation is the ingestion of an extended release formulation, which is pharmaceutically designed to slowly dissolve in the gastrointestinal tract and provide for ongoing sustained release of the active drug product as opposed to immediate release of the drug. Other drug substances can demonstrate the "slow release" profile without having been formulated in a special sustained release dosage form. Examples of these drug "bezoars" include salicylates and barbiturates as well as formulations of iron supplements. The presence of a drug bezoar or concretion can be dangerous because, without serial drug concentration measurements, the treating team could erroneously stratify a patient based on the initial measured plasma concentration and be unprepared for severe toxicity or prolonged toxicity time course not expected from the initial concentration alone.

The use of L-carnitine is an example of the application of basic biochemical knowledge to apply and effective therapeutic

intervention. In the case of valproic acid intoxication, the biochemical effects of valproate on fatty acid metabolism in liver mitochondria, specifically the depletion of L-carnitine, are thought to be causative for the hyperammonemia often observed in moderate and severe cases of valproic acid intoxication (Bohan et al., 2001; Lheureux and Hantson, 2009). Based on these findings and other experimental data, the FDA has approved the use of IV L-carnitine for the treatment of valproic acid poisoning in the setting of hepatotoxicity, hyperammonemia, large overdoses of valproate by history, or measured serum concentrations of valproic acid exceeding 450 mcg/mL.

Finally, the benefit of employing multiple methods simultaneously to enhance the elimination of a toxicant is also demonstrated in this case example. The total body clearance of valproic acid is known to be enhanced when serial oral activated charcoal is administered (Table 33-7). Hemoperfusion, or the more available method of hemodialysis has been shown to increase the total body clearance of valproic acid in overdose (Guillaume et al., 2004). This recommendation is based, in part, on the finding that the plasma protein binding of valproic acid is easily saturated, and in large overdoses, the free fraction (unbound) drug increases from 10% to more than 30%, making more of the drug available for effective removal during hemodialysis. Both modalities were likely beneficially employed in this potentially fatal valproic acid ingestion.

Salicylate

A 48-year-old female is brought to the ED by ambulance approximately 2 hours after a witnessed ingestion of approximately 35 aspirin tablets (each 325 mg) at home in an apparent suicide attempt. The patient complained of upper abdominal discomfort, nausea, and ringing in her ears (tinnitus) and reported one episode of spontaneous emesis at home before transport. The patient has a significant past medical history for major depression disorder, mild osteoarthritis, and hypothyroidism. Her current medications include the antidepressant agent sertraline, 50 mg per day and for hypothyroidism, levothyroxine 100 mcg per day. The patient has been a heavy cigarette smoker (1.5 packs per day) for at least 20 years. No other information about potential illicit substance or alcohol use is available.

Upon arrival in the ED, the vital signs were blood pressure 130/74 mm Hg, pulse 113/min, respiratory rate elevated at 28/min, and body temperature slightly elevated at 38.0°C. She was awake, but oriented only to person. The remainder of the physical examination was significant for slightly dilated pupils (4 mm with normal reactivity to light); heart and lung examinations revealed an increased heart rate and a normal lung exam; the abdominal examination revealed normal bowel sounds and slight epigastric tenderness; no organomegaly or masses were detected. The rectal examination was normal; the stool was without detectable gross or occult blood. Neuro examination was altered mental status, nonfocal with a diminished gag reflex.

Clinical laboratory analysis upon arrival in the ED found the following abnormalities: white blood cell count mildly elevated, serum potassium was slightly low at 3.1 mEq/L, arterial pH 7.15 and serum bicarbonate 11 mEq/L, consistent with a significant metabolic acidosis, anion gap calculation was 29 (normal < 12). At 2.5 hours after the reported ingestion time, salicylate was 36 mg/dL (therapeutic concentrations 10 to 30 mg/dL), acetaminophen was not detected, serum creatinine 1.9 mg/dL, the urine pH was 5.0, and the urine toxicology screen was negative. Chest and abdominal radiographs were normal.

In the ED the patient received normal saline IV and two bolus dosages of 50 mEq sodium bicarbonate to treat her acidosis. IV anti-emetics were given for nausea. At 6 hours post ingestion, the salicylate level was 51.4 mg/dL and no therapeutic action was taken. Five hours later (approximately 11 hours post ingestion) the patient became restless and displayed a tremor in her upper extremities and cramps in her legs. The vital signs at that time were blood pressure 150/105 mm Hg, pulse 144/min, respiratory rate elevated at 30/min, and body temperature slightly elevated at 38.5°C. A salicylate level at that time was 81 mg/dL. Thirteen hours after presentation the patient became significantly agitated, the heart rate increased to 224/min. An arterial blood gas demonstrated pH 7.25, pCO_2 12 mm Hg, and calculated serum bicarbonate 6.6 mEq/L, indicating that the significant metabolic acidosis has continued. Endotracheal intubation and mechanical ventilation were initiated; hemodialysis was not performed on this patient. Following a dose of IV labetalol, given in an attempt to control heart rate, the patient suffered a cardiac arrest from which she could not be resuscitated.

This unfortunate case demonstrates several potential pitfalls in the management of serious salicylate ingestion. First, the witnessed dose ingested was 35 tablets, each containing 325 mg, or more than 11 g of salicylate, which by risk stratification by estimated dose ingested should have alerted the ED staff that this ingestion was very likely to result in severe toxicity. The initial salicylate level was just above the upper limit of normal therapeutic values for salicylate. This lower than expected laboratory result may have steered the ED away from considering this to be a serious and potentially fatal ingestion and toward the obvious under-treatment that occurred. Gastric decontamination did not occur for unclear reasons. Perhaps the ED team assumed that the reported spontaneous emesis was sufficient to prevent significant absorption of the toxicant. Furthermore, the rising salicylate levels over time were apparently overlooked. This phenomenon is commonly seen with extended release formulations (not a factor in this case) or when there is the formation of a drug bezoar. Salicylates, in overdose, are well-known to form drug bezoars in the proximal gastrointestinal tract, which slowly dissolve over time, resulting in rising serum concentrations of salicylate over time. The result of formation of a drug bezoar is that, instead of rapid absorption and a relatively short apparent half-life, the ongoing absorption creates a prolonged and increasing systemic exposure profile for the drug being released from the bezoar. The end result is that the time course to peak toxic effects is delayed. Adequate dosage of activated charcoal upon arrival in the ED, and perhaps use of multi-dose activated charcoal, would likely have reduced the amount of salicylate reaching the systemic circulation. The administration of two bolus doses of sodium bicarbonate was certainly inadequate to overcome the systemic acidosis observed and achieve the needed alkalinizing of the urine to enhance salicylate elimination. The patient should have received a continuous IV sodium bicarbonate infusion with tracking of her urine output and pH with a target pH of 8 for the urine. Involvement of Nephrology consultants to initiate hemodialysis to facilitate salicylate elimination should have also taken place once rising plasma concentrations of salicylate, coincident with clinical deterioration were apparent. In summary, this case reinforces the importance of timely application of the basic, stepwise, procedures available to treat severe, poison-induced toxicity, and demonstrates the potential consequences of underestimating poisoning severity.

SUMMARY

The practice of Clinical Toxicology encompasses the expertise of the specialties of Medical Toxicology, Applied Toxicology, and Clinical Poison Information Specialists. Basic and clinical science continues to provide new information that allows for more effective diagnosis and treatment of the poisoned patient. The evolution of the poison control (information) center and regional poisoning

treatment centers has greatly aided advances in the field of Clinical Toxicology. The incorporation of evidence-based, outcome-driven practice recommendations has improved and standardized the evaluation of treatment modalities for poisonings. Application of a stepwise approach to the poisoned patient as described in this chapter remains an essential approach to the effective evaluation and treatment of the poisoned patient. This methodically performed, clinical diagnostic and therapeutic approach applied in a parallel fashion to the poisoned patient is essential, especially when the medical history is absent or likely unreliable. Skillful use of antidotes is an important component of the practice of Medical Toxicology. Continued research will increase the repertoire of effective treatments for poisoning and ultimately improve patient outcomes.

INTRODUCTION

Those who work full time over a working lifetime will spend about 94,000 hours in the workplace. If that workplace is dusty or laden with chemicals or allergens, it has the potential to induce disease. The higher the exposures, the greater the likelihood of disease. For centuries scholars have recognized that the work environment plays a significant role in the occurrence of adverse human health effects. Early writings by Ulrich Ellenbog (1435 to 1499), Agricola (1494 to 1555), and Paracelsus (1492 to 1541) revealed the toxic nature of exposures in mining, smelting, and metallurgy. A systematic treatise by Ramazzini (1633 to 1714) described the hazards as they applied to workers in over 50 common trades including miners, chemists, tinsmiths, tanners, pharmacists, grain sifters, stonecutters, sewage workers, and even corpse bearers. Legislation to protect worker health began in England with the Factory Act of 1833 which established a factory inspectorate and limited child laborers 9 to 13 years old to a 48-hour work week and 14- to 18-year olds to a 68-hour work week.

Today we continue to be concerned with occupational health and safety in a wide variety of work environments and child labor remains a concern worldwide. There are an estimated 151.6 million children between the ages of 5 and 17 engaged in child labor and half of them do hazardous work (ILO, 2017). Although occupational settings in developed countries are safer now than in the past, the levels of risk deemed acceptable have decreased while the recognition of the causal link of exposures to chronic diseases or diseases with long latencies has increased. As new hazards arise with the emergence of new technologies, we must be prepared to assess the risks and protect the health of workers. With increased globalization and rising prosperity in many middle-income countries, there exists a responsibility to extend health protections to workers in developing nations who too often bear the burden of high exposures to occupational toxicants.

Occupational toxicology is the application of the principles and methodology of toxicology toward understanding and managing chemical and biological hazards encountered at work. The objective of the occupational toxicologist is primary prevention, that is to prevent adverse health effects in workers that could arise from exposures in their work environment. Because nonoccupational exposures can act as confounders or can increase the susceptibility of individual workers, occupational toxicologists must evaluate the entire spectrum of exposures experienced by the work force under consideration. Occupational toxicology is a discipline that draws on industrial hygiene, epidemiology, occupational medicine, and regulatory toxicology. The occupational toxicologist must have an intimate knowledge of the work environment and be able to recognize and prioritize exposure hazards. Because the work environment can present exposures to complex mixtures, the occupational toxicologist must also recognize those that are particularly hazardous when occurring in combination.

It is often difficult to establish a causal link between a worker's illness and job. First, the clinical manifestations of occupationally induced diseases are often indistinguishable from those arising from nonoccupational causes. Second, there may be a protracted but biologically predictable latent interval between exposure and the expression of disease. Third, diseases of occupational origin may be multifactorial with other environmental factors or personal (e.g., genetic, epigenetic, or behavioral) risk factors contributing to the disease process. Nevertheless, studies have repeatedly shown that the dose of toxicant is a strong predictor of the likelihood, severity, and type of health effect.

WORKPLACES, EXPOSURES, AND STANDARDS

The Nature of the Work Force

The world's labor force totals 3.45 billion people (World Bank, 2017). This includes 803 million workers in China and 511 million workers in India. Approximately 31.3% of the global work force, some 1.1 billion people, work in agricultural production. Many of these workers are engaged in subsistence agriculture and fewer than half are waged workers (ILO, 2014). In contrast, the demographics and distribution of the work force in industrialized nations has undergone a progressive shift over the past three decades, moving away from jobs in heavy industry and agriculture toward jobs in the service sector and high-technology industries. In some instances, the manufacturing jobs have moved to less developed countries with less stringent worker health protection. There are currently 153 million people in the United States in the civilian, paid work force (seasonally adjusted data). The civilian labor force participation rate is 62.9% (USDL, 2017c), a figure that has grown markedly over the past 50 years owing to the increased entry of women into the labor force. The countries of the EU have an estimated 234 million workers (European Commission, 2017), and Japan has about 66 million (Japan Monthly Statistics, 2017). The 1.3 billion workers in the labor force of China and India includes many jobs in manufacturing, minerals extraction, agriculture, and waste processing (including electronic waste).

Fig. 34-1 shows the breakdown of employment in the United States. This illustrates that there are about 22.2 million workers (14.9%) engaged in manufacturing, construction, mining and logging, and agriculture—occupations that have the potential for significant exposure to chemical and biological agents. Furthermore, there are occupations in the service sector, such as automobile repair; other repair and maintenance; work in gasoline stations, pipeline transportation, truck and rail transportation; waste management and remediation services; and employment in botanical gardens that can also include exposures to hazardous chemicals. Service-producing occupations (including government jobs) account for the majority (85.1%) of U.S. jobs. On average, employees in the service sector work 6.4 fewer hours per week than in the goods-producing sector. Farm work employs an estimated 2.14 million workers 16 years of age and older, and the U.S. Bureau of Labor Statistics has documented an average of 40.4 hours worked per week. Work in agriculture is markedly different from most other occupations in four fundamental ways. First, 44% of those employed in agriculture are self-employed or unpaid family members. Second, the overwhelming majority of farm establishments (90%) are small family farms with fewer than 20 employees and annual gross cash farm income less than $350,000 (USDA, 2017). Third, although the annual national average hours worked per week is 40.4, many farmers, ranchers, and farm workers have periods (e.g., harvest time) when they work as many as 20 hours per day, 7 days per week. Fourth, according to a 1998, one-time U.S. government survey, there are in excess of 290,000 children who identify agricultural work as their major employment (GAO/HEHS, 1998). Department of Labor data indicate that, on average, 128,500 hired farm workers between the ages of 14 and 17 were working annually in crop production. The U.S. Fair Labor Standards Act establishes a 16-year minimum age for those occupations in agriculture that the Secretary of Labor finds and declares to be particularly hazardous. The presence of children in the work force has important ramifications for body burdens, disease latency, toxicokinetics, and biotransformation of toxicants.

Determinants of Dose

Dose is typically defined as the amount of toxicant that reaches a target tissue over a defined time span and is available for interactions with metabolic processes. In occupational environments, *exposure* is often used as a proxy for *dose*. The response to a chemical is dependent upon both host factors and dose. Fig. 34-2 illustrates the pathway from exposure to subclinical disease or to adverse health effect and suggests that there are important modifying factors: contemporaneous exposures, genetic and epigenetic susceptibility, age, gender, nutritional status, and behavioral factors. These modifying factors can influence whether a worker remains healthy, develops subclinical disease that is repaired, or progresses to frank illness. Workplace health protection and surveillance programs (shown in blue) can reduce exposures, disrupt the exposure-dose pathway, or identify internalized dose and early effects before irreparable

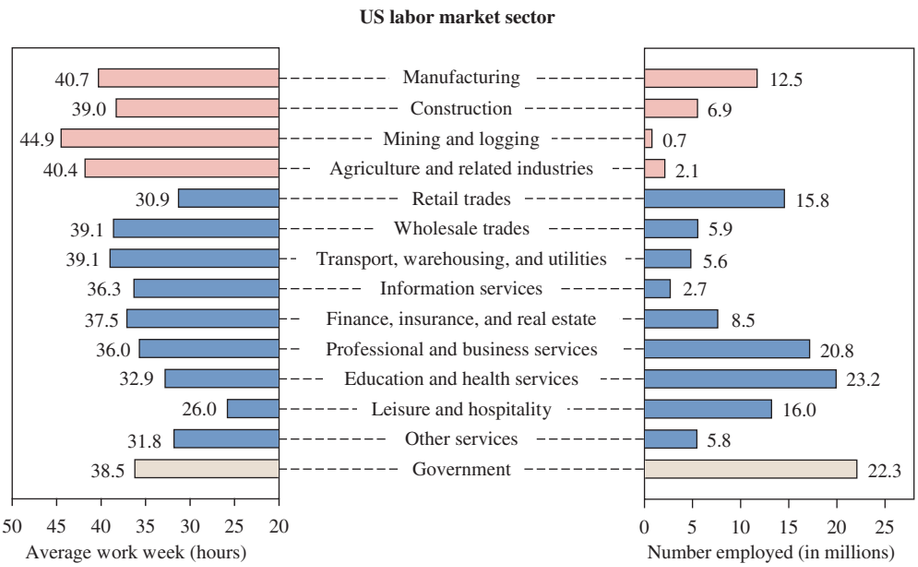

Figure 34-1. *Hours worked and number employed in the U.S. civilian labor market.* (From USDL [2017a, 2017b, 2017c].)

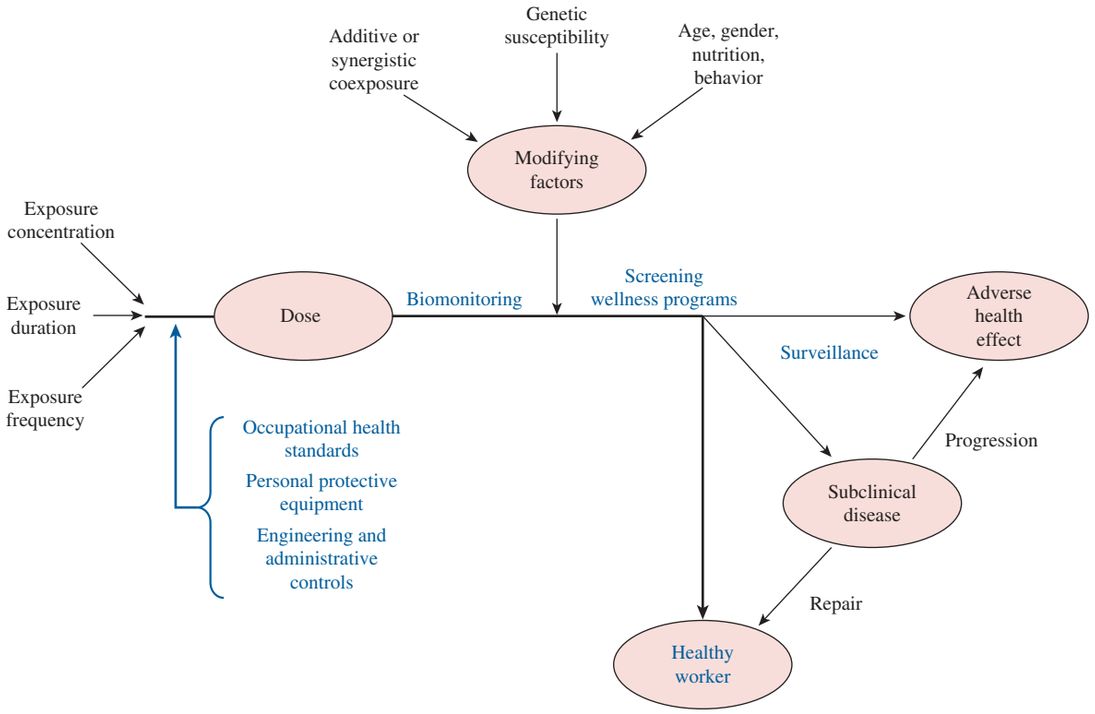

Figure 34-2. *Pathway from exposure to disease, showing modifying factors and opportunities for intervention.*

disease develops. These programs help to ensure a safe workplace and a healthier work force.

As illustrated in Fig. 34-2, dose is a function of exposure concentration, exposure duration, and exposure frequency. Individual and environmental characteristics can also affect dose. Exposure assessment is the process of quantifying the intensity, frequency, and duration of exposures and their determinants in order to better estimate dose. Table 34-1 indicates determinants of dose for exposure via the inhalation and dermal routes. For determining inhalation exposures, environmental conditions such as concentration, particle size distribution, and properties of the chemical are important. However, respiratory rate and breathing volume as well as other host factors contribute. Protection afforded by personal protective equipment (especially respirators) will reduce but not eliminate exposure. The degree of exposure reduction for a particular respirator (the workplace protection factor) varies with respirator design, fit, maintenance, manner of use, and environmental conditions from less than 5 to 10,000. A respirator with a workplace protection factor of 10, when used properly, will reduce particulate matter concentrations inside the mask to one-tenth that outside the mask. A commonly used two-strap fiber respirator for lowering particulate matter exposure, the N95, should reduce exposures by 95% but may fail to meet this criterion for submicron aerosols (Balazy et al., 2006).

Dermal exposures depend upon toxicant concentration; work conditions, including the degree and duration of wetness; and the ambient conditions at the work site (Table 34-1). Some determinants of dermal dosing relate to the physicochemical properties of the chemical as they affect the percutaneous absorption rate. These include solubility, temperature, pH, molecular size, and chemical characteristics of the vehicle. Host factors also influence dermal absorption and distribution. Important factors include the surface area of the skin that is exposed, the integrity of the skin, blood flow, and biotransformation. Because the stratum corneum, the outer layer of the epidermis, is the principal barrier to dermal uptake, the thickness of this layer in the exposed area has great significance. As an example, the absorption of hydrocortisone through the plantar foot arch is only 4% than through the back and 0.3% than through scrotal skin (Bason et al., 1991). A classic human in vivo study (Maibach et al., 1971) using the pesticide parathion demonstrated

Table 34-1

Determinants of Toxicant Dose

Concentration in air, droplets, or solutions
Degree and duration of wetness
Integrity of skin
Percutaneous absorption rate
Region of skin exposed
Surface area exposed
Preexisting skin disease
Temperature in the workplace
Vehicle for the toxicant
Presence of other chemicals on skin

a 12-fold range in percutaneous absorption between the anatomical site with the highest (scrotum) to that with the lowest (forearm) percent of dose absorbed. Trabaris et al. found 10-fold higher dermal fluxes of chloracetonitrite, a disinfection byproduct, for excised skin from the torso and dorsum as compared to the palm and scalp (Trabaris et al., 2012). The use of protective gloves and clothing or aprons and the application of barrier creams can greatly reduce exposure. For maximal protection, it is important that the glove be constructed of material tailored to the toxicant(s) of concern.

Occupational Exposure Limits

One of the roles of the occupational toxicologist is to contribute data to the process of establishing standards or determining the appropriateness of those standards. Workplace exposure limits exist for chemical, biological, and physical agents and are recommended as guidelines or promulgated as standards in order to promote worker health and safety. For chemical and biological agents, exposure limits are expressed as acceptable ambient concentration levels (occupational exposure limits [OELs]) or as concentrations of a toxicant, its metabolites, or a specific marker of its effects in biological systems (biological exposure indices).

OELs are established as standards by regulatory agencies or as guidelines by research groups or professional organizations. In the United States, the Occupational Safety and Health Administration (OSHA) under the Department of Labor promulgates legally enforceable standards known as permissible exposure limits (PELs). These standards are determined and supported by the best scientific evidence available and assure "to the extent feasible … that no employee will suffer material impairment of health or functional capacity" with regular exposure "for the period of his working life." OSHA has defined an 8-hour time-weighted average (TWA) PEL (U.S. Federal Register, 1992) as the "employee's average airborne exposure in any 8-hour work shift of a 40-hour work week which shall not be exceeded." The TWA PEL is established as the highest level of exposure to which an employee may be exposed without incurring the risk of adverse health effects (OSHA, 1995). Although approximately 500 PELs have been promulgated, there are not enough to regulate exposures to the vast number of compounds to which workers are exposed, and some of the existing PELs do not reflect current knowledge.

The National Institute for Occupational Safety and Health (NIOSH), under the Centers for Disease Control and Prevention, publishes recommended exposure limits (RELs) that are more frequently updated and are generally more stringent than PELs. NIOSH also performs research and disseminates information on workplace hazards and their prevention. Most developed countries have governmental inspectorate agencies analogous to OSHA that are responsible for establishing and enforcing OELs. In some countries, the insurance system also plays a significant role.

The European Commission has established legally enforceable binding occupational exposure limit values (BOELV) and biological limit values (BLV) for the protection of health and safety in the workplace. Socioeconomic and technical feasibility factors are also considered in setting these values. The OELs are established based on recommendations of the Scientific Committee on Occupational Exposure Limits (SCOEL), which evaluates published scientific data on hazardous compounds for regulation and provides assessment of exposure limits that "it believes will protect workers from chemical risks" (European Commission, 1995, 1998). Indicative Occupational Exposure Limit Values (IOELVs) are non-binding health-based OELs that do not consider technical or economic feasibility. A first list of IOELVs was established in 2000 followed by second (European Commission, 2006) and third lists in 2006 and 2009, respectively (European Commission, 2009). EU member countries may not promulgate OELs less stringent than these values.

The American Conference of Governmental Industrial Hygienists (ACGIH) is a non-profit scientific association that publishes OELs for chemicals and for physical agents. These take the form of threshold limit values (TLVs™) and biological exposure indices (BEIs™). They are frequently revisited and generally reflect current knowledge in occupational toxicology and industrial hygiene. They are developed as guidelines and are not enforceable standards; however, many industries adopt TLVs and BEIs as internal OELs. As stated by the ACGIH, "The TLVs and BEIs represent conditions under which ACGIH believes that nearly all workers may be repeatedly exposed without adverse health effects" (ACGIH, 2017). These guidelines are health based and do not include consideration of technical feasibility or economic effects of implementation.

Three types of TLVs are suggested, depending on the time scale of adverse effects inducible by the toxicants. The time-weighted average TLV (TLV-TWA) is an OEL for exposures averaged over an 8-hour day, 5-day work week regimen. These are generally applied to toxicants that exert their effects over long periods. The short-term exposure limit (TLV-STEL) is an OEL for a 15-minute measurement period. The TLV-STEL should not be exceeded in any 15-minute sampling window and there should be 60 minutes or more between exposures in this range. The ceiling limit (TLV-C) represents a concentration that should never be exceeded. These are usually applied to toxicants that cause acute effects (such as asphyxia or potent sensory irritation) and for which real-time monitoring devices are available. BEIs are guidance values for biological monitoring and represent "levels of determinants that are most likely to be observed in specimens collected from healthy workers who have been exposed to chemicals to the same extent as workers with inhalation exposure at the Threshold Limit Value" (ACGIH, 2016). BEIs are recommended for analysis of urine, blood, and exhaled air. While hair, fingernails, adipose tissue biopsies, and other specimens are used in research and forensic toxicology, there are no BEIs for these.

It is important to recognize that OELs do not correspond to exposure conditions devoid of health risk. The concept of acceptable exposure level must be understood as the level of exposure below which the probability of impairing the health of the exposed workers is acceptable. The process of deciding what is an acceptable risk to occupational or environmental hazards blends the scientific disciplines of exposure assessment and toxicology with often vexing policy issues. Historically, acceptable risk in a society is related to the general health of the population and to a host of factors that influence how risks are perceived. To determine that the risks from an occupational hazard are acceptable, it is necessary to characterize the hazard, identify the potential diseases or adverse outcomes, and establish the relationship between exposure intensity or dose and the adverse health effects. If biological markers of exposure or early reversible effects are identified, this can aid in the risk-assessment process.

OCCUPATIONAL DISEASES

Routes of Exposure

Diseases arising in occupational environments involve exposure primarily through inhalation, ingestion, or dermal absorption. In the vast majority of work environments, inhalation of toxicants is a primary concern. Inhalation exposures can occur with gases,

vapors, liquid aerosols, particulate aerosols, fumes, and mixtures of these. Dermal exposures are also important and can arise from airborne materials as well as liquids splashed onto the skin, immersion exposures, or from material handling.

Additional exposure hazards exist for infectious agents. Exposures leading to occupational infections may arise through inhalation or ingestion of microorganisms but can also arise from needle-sticks in health-care workers or through insect bites among farmers, natural resource workers, and others employed out of doors. Additionally, poisonings from toxic plants or venomous animals can occur through skin inoculation (e.g., zookeepers, horticulturists, or commercial divers).

Agents Associated With Diseases

There are a myriad of agents responsible for occupational diseases. While some act on a particular organ such as the liver or kidney, others can affect multiple organ systems. Table 34-2 presents a list of the major occupational diseases and examples of agents that cause them. This is not intended to be all-inclusive. Rather it is meant to highlight what are historically the most prevalent and widely recognized occupational diseases plus those that continue to be prevalent in the workplace. The toxicants listed are those for which there is a strong association with the disease or the most conclusive data to support causality. Examples are shown for cancer and for diseases of the lung and airways, heart, liver, kidney, skin, nervous system, immune system, and reproductive system. Several examples of occupational infectious diseases are also listed to highlight the fact that, in many work settings, infectious agents may constitute the major hazard and may coexist with chemical hazards. Concurrent chemical exposures may increase susceptibility to infectious agents. Most of the occupational diseases listed in Table 34-2 are associated with industrial chemicals. These are discussed in other chapters throughout this book.

Table 34-2

Examples of Occupational Diseases and the Toxicants That Cause Them

ORGAN SYSTEM OR DISEASE GROUP	DISEASE	CAUSATIVE AGENT
Lung and airways	Acute pulmonary edema, bronchiolitis obliterans	Nitrogen oxides, phosgene, diacetyl
	Allergic rhinitis	Pollens, fungal spores
	Asphyxiation	Carbon monoxide, hydrogen cyanide, inert gas dilution
	Asthma	Toluene diisocyanate, α-amylase, animal urine proteins
	Asthma-like syndrome	Swine barn environments, cotton dust, bioaerosols
	Bronchitis, pneumonitis	Arsenic, chlorine
	Chronic bronchitis	Cotton dust, grain dust, welding fumes
	Emphysema	Coal dust, cigarette smoke
	Fibrotic lung disease	Silica, asbestos
	Hypersensitivity pneumonitis	Thermophilic bacteria, avian proteins, pyrethrum, *Penicillium, Aspergillus*
	Metal fume fever	Zinc, copper, magnesium
	Mucous membrane irritation	Hydrogen chloride, swine barn environments
	Organic dust toxic syndrome	"Moldy" silage, endotoxin
	Reactive airways dysfunction syndrome	Ammonia, chlorine, acetic acid
	Upper respiratory tract inflammation	Endotoxin, peptidoglycan, glucans, viruses
Cancer	Acute myelogenous leukemia	Benzene, ethylene oxide
	Bladder cancer	Benzidine, 2-naphthylamine, 4-biphenylamine
	Gastrointestinal cancers	Asbestos
	Hepatic hemangiosarcoma	Vinyl chloride
	Hepatocellular carcinoma	Aflatoxin, hepatitis B virus
	Mesothelioma, lung carcinoma	Asbestos, arsenic, radon, bis-chloro methyl ether
	Skin cancer	Polycyclic aromatic hydrocarbons, ultraviolet irradiation
Skin	Allergic contact dermatitis	Natural rubber latex, isothiazolins, poison ivy, nickel
	Chemical burns	Sodium hydroxide, hydrogen fluoride
	Chloracne	TCDD†, polychlorinated biphenyls
	Irritant dermatitis	Sodium dodecyl sulfate
Nervous system	Cholinesterase inhibition	Organophosphate insecticides
	Neuronopathy	Methyl mercury
	Parkinsonism	Pesticides, polychlorinated biphenyls, trichloroethylene, carbon disulfide
	Peripheral neuropathy	*N*-hexane, trichloroethylene, acrylamide
Immune system	Autoimmune disease	Vinyl chloride, silica
	Hypersensitivity	See entries for allergic rhinitis, asthma, hypersensitivity pneumonitis, allergic contact dermatitis
	Immunosuppression	TCDD†, lead, mercury, pesticides
Renal disease	Indirect renal failure	Arsine, phosphine, trinitrophenol
	Nephropathy	Paraquat, 1,4-dichlorobenzene, mercuric chloride

(*continued*)

Table 34-2

(Continued)

ORGAN SYSTEM OR DISEASE GROUP	DISEASE	CAUSATIVE AGENT
Cardiovascular disease	Arrhythmias	Acetone, toluene, methylene chloride, trichloroethylene
	Atherosclerosis	Dinitrotoluene, carbon monoxide
	Coronary artery disease	Carbon disulfide
	Cor pulmonale	Beryllium
	Systemic hypotension	Nitroglycerine, ethylene glycol dinitrate
Liver disease	Fatty liver (steatosis)	Carbon tetrachloride, toluene
	Cirrhosis	Arsenic, trichloroethylene
	Hepatocellular death	Dimethylformamide, TCDD[†]
Reproductive system	Male	Chlordecone (Kepone), dibromochloropropane, hexane
	Female	Aniline, styrene
	Both sexes	Carbon disulfide, lead, vinyl chloride
Infectious diseases[*]	Arboviral encephalitides	Alphavirus, Bunyavirus, Flavivirus
	Aspergillosis	*Aspergillus niger, A. fumigatus, A. flavus*
	Cryptosporidiosis	*Cryptosporidium parvum*
	Hepatitis B	Hepatitis B virus
	Histoplasmosis	*Histoplasma capsulatum*
	Legionellosis	*Legionella pneumophila*
	Lyme disease	*Borrelia burgdorferi*
	Psittacosis	*Chlamydia psittaci*
	Tuberculosis	*Mycobacterium tuberculosis hominis*

[*]*For more on occupational infectious diseases, see Douwes et al. (2003).*
[†]*TCDD = 2,3,7,8-tetrachlorodibenzo-para-dioxin.*

Table 34-3 lists 39 agents that are known by the International Agency for Research on Cancer (IARC) to be carcinogens in humans (Group 1) and for which there has been or is currently extensive occupational exposure. This list includes agents such as asbestos, arsenic, benzene, vinyl chloride, and coal tars. IARC Group 1 refers to agents or mixtures that are known to be carcinogenic to humans based on sufficient epidemiologic evidence usually accompanied by limited or sufficient animal evidence.

Occupational Respiratory Diseases

Because inhalation generally represents the most significant route of exposure, many of the major occupational diseases affect the lung and airways. These diseases have been studied extensively and are largely responsible for the creation of the occupational regulatory framework. Deaths due to occupational lung diseases such as asbestosis, coal workers' pneumoconiosis, silicosis, byssinosis, and occupational asthma have been recognized for centuries and led to important legislation such as the U.S. Occupational Safety and Health Act (1970). These occupational lung diseases continue to have significant associations with morbidity and mortality worldwide but are diminishing steadily in the United States and Europe. Table 34-4 lists the U.S. age-adjusted death rate and annual deaths for 2014 and illustrates that while the death rates are fairly low, there are still about 1477 deaths per year attributable to asbestos, silica, coal dust, and other pneumoconiotic dusts; 2786 malignant mesothelioma deaths; and 141 deaths from hypersensitivity pneumonitis. However, fatalities are just the tip of the iceberg as some occupational lung diseases exhibit slow progression yet may still be debilitating. Every year in the United States, there are 20,000 hospital discharges related to cases of asbestosis and 188,000 coal workers receive federal Black Lung Benefits (NIOSH, 2017c). The U.S. Mine Safety and Health Administration has compiled data on inspector- and mine operator-collected samples in coal mining operations and found that 29.3% of these exceeded the PEL for respirable quartz and 7.5% were over the PEL for respirable coal dust.

Many of the diseases listed in Table 34-2 are known by other names that refer to a particular occupation or agent. One example is hypersensitivity pneumonitis, an allergic lung disease marked by interstitial lymphocytic pneumonitis and granulomatous lesions. Hypersensitivity pneumonitis is also known as extrinsic allergic alveolitis, farmer's lung disease, bagassosis (sugar cane), humidifier fever, Japanese summer house fever, pigeon breeder's lung, and maple bark stripper's lung, depending upon the occupational setting in which it arises. Although we often think of these as the same disease, it is important to recognize that the exposures and physiologic responses they induce are complex and may differ in the manifestation of the disease.

The U.S. Bureau of Labor Statistics tracks data for non-fatal occupational injuries and illnesses of which there were 3.3 million in 2009. The vast majority of these were injuries (e.g., falls, slips, strains, sprains, back injuries, and roadway incidents), but there were still over 187,900 occupational illnesses reported in 2015 (USDL, 2015). There were 17,200 reported respiratory conditions arising from exposure to toxic agents and dust diseases of the lung. The former category includes pneumonitis, pharyngitis, rhinitis, and acute lung congestion. Table 34-5 shows data for rates and cases in 2015 by industry division. Poisonings were rare whereas skin diseases occurred at rates as high as 4.3 per 10,000 workers per year. The manufacturing sector accounted for approximately 22% of all occupational illnesses. Industry codes with the highest respiratory condition incidence rates were aquaculture (94.0 per 10,000); oilseed and grain farming (33.7 per 10,000); coal mining (24.1 per 10,000); roasted nuts and peanut butter manufacturing (17.1 per 10,000); and copper, nickel, lead, and zinc mining (14.2 per 10,000). The rate for chemical manufacturing was much lower, 1.7 cases per 10,000 workers, down by 50% since 2000.

Table 34-3

Occupational Exposure Agents Classified by IARC as Group 1 Definite Human Carcinogens

AGENT	INDUSTRIES AND OCCUPATIONS WHERE SOME WORKERS MAY BE EXPOSED
Particulate matter	
Asbestos	Miners, abatement workers, construction workers, sheet metal workers, steam fitters, shipyard workers
Crystalline silica (quartz or cristobalite)	Stone and ceramics industry, foundries, construction, abrasives manufacturing
Erionite	Waste treatment workers, building materials manufacturing
Talc containing asbestiform fibers	Ceramics industry
Wood dust	Wood and wood-products industries, pulp and paper industry, wood working trades
Metals	
Arsenic and arsenic compounds	Miners, nonferrous metal smelting, arsenical pesticide manufacturers and applicators
Beryllium	Specialty metallurgy workers, avionics, electronics, nuclear industry
Cadmium and cadmium compounds	Cadmium smelting, battery production, dyes and pigment making, electroplating
Gallium arsenide	Microelectronics manufacturing
Hexavalent chromium compounds	Chromate production plants, dye and pigment making, welders, tanners
Nickel compounds*	Nickel smelting, welding
Organic chemicals	
Aflatoxins	Animal feed industry, grain handling and processing
4-Aminobiphenyl	Chemical industry, dyestuffs and pigment manufacturing
Benzene	Refineries, shoe industry, chemical, pharmaceutical and rubber industry, printing industry
Benzidine	Chemical industry, dyestuffs and pigment manufacturing
Benzo(*a*)pyrene	Coke oven emissions, coal tar pitch volatiles, diesel exhaust, ETS
Bis(chloromethyl) ether and chloromethyl ether (technical grade)	Chemical industry, laboratory reagent, plastic manufacturing
1,3-Butadiene	Chemical industry, petrochemical plants, styrene–butadiene rubber manufacturing
Coal tars and pitches	Coke production, coal gasification, refineries, foundries, road paving, hot tar roofing
Ethylene oxide	Chemical industry, dry vegetable fumigation, hospital sterilizing
Formaldehyde	Textiles, composite wood industry, chemical industry, medical laboratories
4,4′-Methylenebis(2-chloroaniline) [MOCA]	Epoxy resin manufacturing, polyurethane product fabrication
Mineral oils, untreated and mildly treated	Metal machining and honing, roll steel production, printing
2-Naphthylamine	Chemical industry, dyestuffs and pigment manufacturing
2,3,4,7,8-Pentachlorodibenzofuran	Hazardous waste processing, chlorophenoxy herbicide production and use, pulp and paper industry
3,4,5,3′,4′-Pentachlorobiphenyl‡ [PCB126]	Hazardous waste processing, waterway dredging, transformer handling, pulp and paper industry
Shale oils or shale-derived lubricants	Mining and processing, cotton textile industry
Soot	Chimney sweeps, heating and ventilation contractors, firefighters, metallurgical workers
2,3,7,8-Tetrachlorobibenzo-*para*-dioxin (TCDD)	Hazardous waste processing, chlorophenoxy herbicide production and use, pulp and paper industry
Vinyl chloride	Plastics industry, production of polyvinyl chloride products and copolymers
Other agents with occupational exposure	
Environmental tobacco smoke (ETS)	Restaurant, bar and entertainment industry; other smoke-exposed workers
Occupational exposures as a painter	Commercial painting
Leather dust	Garment industry, auto seat fabrication, saddle and tack manufacturing,
Magenta dye (rosaniline, pararosaniline)	Dye manufacture, textile dying, commercial art and printing
Mustard gas	Production, soldiers, some research laboratories
Exposures in the rubber industry	Work in rubber manufacturing industries
Strong inorganic acid mists containing sulfuric acid	Steel industry, petrochemical industry, fertilizer industry, pickling industry
Physical agents	
Ionizing radiation†	Radiology and nuclear medicine staff, nuclear workers, miners, hazardous waste workers
Solar radiation	Farmers, gardeners and landscapers, lifeguards, construction workers

**Certain combinations of nickel oxides and sulfides.*

†Includes x-rays, γ-rays, neutrons, radon gas, and α and β particle-emitting substances internally deposited.

‡PCBs as a class are listed by IARC as Group 1, carcinogenic to humans as of 2016.

Table 34-4

U.S. Deaths and Age-Adjusted Death Rates Attributed to Selected Occupational Lung Diseases for U.S. Residents Age 15 and Over, 2014

DISEASE	NUMBER OF DEATHS†	DEATH RATE PER MILLION WORKING AGE PEOPLE
Asbestosis	1221	4.39
Coal workers pneumoconiosis	363	1.26
Silicosis	84	0.30
Byssinosis	2	0.01
Other pneumoconioses*	139	0.48
Malignant Mesothelioma	2786	9.89
Hypersensitivity pneumonitis	141	0.49

**This includes aluminosis, berylliosis, stannosis, siderosis, and fibrosis from bauxite, graphite fibers, wollastonite, cadmium, portland cement, emery, kaolin, antimony, and mica.*
†Includes underlying and contributing cause deaths.
SOURCE: From NIOSH (2017a).

Toxic gas injuries are often characterized by leakage of both fluid and osmotically active proteins from the vascular tissue into the interstitium and airways. Important determinants of the severity and location of injury are the concentration and water solubility of the toxic gas or vapor. Anhydrous ammonia, with its extremely high solubility, primarily damages the eyes, sinuses, and upper airways. The vapors combine with water in the tissue and form ammonium hydroxide, quickly producing liquefaction necrosis. Chemicals with lower solubility, such as nitrogen dioxide, act more on the distal airways and alveoli and take longer to induce tissue damage.

Occupational asthma may be defined as a "disease characterized by variable airflow limitation and/or airway hyperresponsiveness and/or inflammation due to causes and conditions attributable to a particular occupational environment and not to stimuli encountered outside the workplace" (Bernstein et al., 2013). Workplace asthma is generally divided into allergic, non-allergic, and work-aggravated asthma. Data from the NIOSH Work-Related Occupational Lung Disease Surveillance System has shown that 22% of occupational asthma cases represented aggravation of pre-existing asthma by workplace exposures. The U.S. National Health Interview Survey has provided data on the prevalence of asthma based upon usual industry (Table 34-6). These data indicate that asthma prevalence is much higher for female than male workers and is highest in manufacturing of plastics and rubber; electrical equipment and appliances; chemicals; and transportation equipment. Among the service sectors asthma is prevalent among those engaged in health care and social assistance; education; and

personal services. In retail, prevalence is highest among gasoline station workers and employees of furniture and home furnishings stores and businesses selling electronics and appliances.

There are a variety of industries in which there is increased risk of developing work-related asthma. In chemical-based industries, plastic and rubber polymer precursors, diisocyanates, reactive dyes, and acid anhydrides are recognized low-molecular-weight sensitizing compounds. Biocides and fungicides used in metal fabrication and machining, custodial services, lawn and turf growing, and agriculture are also chemicals associated with occupational asthma. A number of metals can induce sensitization and asthma, including chromium, cobalt, nickel, platinum, and zinc. Enzymes pose significant risks for occupational asthma (Heederik et al., 2002). Examples include α-amylase among bakery workers and subtilisin, a protease used in laundry detergents. The enzyme production industry has had to adopt strict environmental and process controls to reduce the incidence of occupational asthma in their production facilities.

Those working with animals or animal products are at increased risk of developing allergy (Elliott et al., 2005) and occupational asthma (Pacheco et al., 2003). Lab animal workers have concurrent exposure to animal allergens and bacterial endotoxin and being allergic modifies the relationship between endotoxin exposure and respiratory symptoms (Newton et al., 2017). Animal handlers, processors, and laboratory technicians who work with animals can become immunologically sensitized to urine or salivary proteins in many vertebrates; proteins in bat guano and bird droppings; animal dander; serum proteins in blood products; dust from horns, antlers, and tusks; or the shells of crustaceans. Very high rates of sensitization can occur in shellfish processors (Glass et al., 1998). Arthropods such as insect larvae, cockroaches, mites, or weevils are recognized inducers of work-related asthma. Plants and plant products (e.g., soy flour, spices, and coffee beans) can also cause asthma among workers. In a variety of occupations, exposure to fungi, especially of the genera *Aspergillus, Penicillium, Rhizopus, Mucor*, and *Paecilomyces*, is associated with allergic rhinitis and asthma. These are especially present in sawmills, woodchip handling, and composting facilities (Eduard et al., 1992; Duchaine et al., 2000). Apart from the contaminating microorganisms, certain woods themselves produce chemical sensitizing agents. Examples include western red cedar, redwood, and some tropical hardwoods.

Asthma emerged in the 1980s as a major occupational health concern among health-care workers. In order to reduce the risk of hepatitis B and other infectious diseases, health-care workers adopted the use of natural rubber latex gloves for barrier protection. Proteins from the latex of the rubber tree, *Hevea braziliensis*, led to immunologic sensitization. Thirteen of these high-molecular-weight

proteins have been characterized as allergens (Bernstein et al., 2003). People with latex allergy may also be sensitive to banana, avocado, chestnut, and kiwi due to cross-reactivity with the latex allergen fragment hevein (Radauer et al., 2011). Many other plants of less commercial value than *Hevea* produce a similar milky fluid when cut and have similar sensitizing properties. A shift to powder-free, nitrile, and vinyl examination gloves has reduced the incidence of latex allergy among health-care workers and patients.

Studies of asthma prevalence in occupational settings with exposure to low-molecular-weight chemicals have suggested prevalence rates of 5% to 10% for toluene diisocyanate (Baur, 1996; Becklake et al., 2006), 3.2% to 18% for anhydrides (Venables et al., 1985; Wernfors et al., 1986), 4% for plicatic acid from western red cedar (Chan-Yeung et al., 1984), and 54% in a platinum refinery (Venables et al., 1989). For high-molecular-weight allergens, prevalence among shellfish processors was estimated at 21% to 26% (Desjardins et al., 1995; Glass et al., 1998), 11% to 44% among lab animal workers (Cullinan et al., 1994; Fuortes et al., 1997; Hollander et al., 1997), and 5% to 7% among bakers exposed to wheat and α-amylase (Heederik et al., 2002).

Agricultural workers exposed to grain dust, cotton dust, or atmospheres in swine or poultry confinement barns may have reduced risk to developing allergy due to innate immune responses to inhaled endotoxin and microorganisms. However, they are at high risk for the development of an asthma-like syndrome. This syndrome is an acute nonallergic airway response characterized by self-limited inflammation with neutrophilic infiltrates and increased pro-inflammatory cytokines and chemokines (e.g., TNFα, IL-6, and IL-8), but it does not include persistent airway hyperreactivity, as in occupational asthma (Schenker et al., 1998). Asthma-like syndrome includes cough, mild dyspnea, fever, malaise, and cross-shift declines in lung function. Endotoxin in combination with other inflammatory bioaerosols is the likely etiologic agent (Douwes et al., 2003).

An emerging area of concern is adverse effects of respiratory exposures to manufactured nanomaterials. There are currently over 1800 consumer products that contain nanotechnology-based materials (Vance et al., 2015). Nanomaterials are engineered structures that have a primary size less than 100 nm in at least one dimension. Airborne nanoparticles generally form agglomerates in which groups of particles are held together by relatively weak forces (e.g., van der Waals). They may also aggregate forming clusters that are fused, sintered, or chemically bonded to one another (Pettibone et al., 2008). Manufactured nanomaterials find applications in electronics, construction materials including wall and floor coverings, cosmetics, drug delivery, medical imaging, food products, packaging materials, textiles, and sporting equipment, to name a few. Occupational exposures occur in the manufacture of the nanomaterials and in their use in fabricating materials and consumer products. Exposures can also occur when nanomaterials are cut or shaped and when product waste is discarded. Engineered nanomaterials may be carbon-based, metal-based, or biological in nature. Biological actions of nanoscaled materials may differ from the comparable bulk materials or micron-sized particles (NIOSH, 2013). Inhaled nanomaterials may induce pulmonary toxicity or they can cause adverse effects in other tissues through adsorption and transport, generation of toxic substances by their dissolution or degradation, or by crossing key physiological barriers, or cell and nuclear membranes (Kim et al., 2011). Mechanisms of nanotoxicity include oxidative stress, inflammation, cytotoxicity, genotoxicity, and developmental toxicity (Adamčaková-Dodd et al., 2014, 2015). Metal and metal-oxide nanoparticles absorb materials from the airway surface fluid and acquire protein coronas that can affect their pulmonary clearance (Konduru et al., 2017). In early 2011, NIOSH issued a new guideline on TiO_2, marking the first instance of two guidelines for the same compound based on particle size. In 2013, NIOSH issued a *Current Intelligence Bulletin* on carbon nanotubes and nanofibers that proposed an REL of 1 $\mu g/m^3$ elemental carbon as an 8-hour time-weighted average (TWA) concentration (NIOSH, 2013). Research programs and regulatory bodies in the United States and the EU are studying the toxicity of nanomaterials in commercial use and conducting human health risk assessments.

Other Occupational Diseases

Occupational diseases of the skin are common but less often fatal than those of the respiratory system. Irritant dermatitis and allergic contact dermatitis have the highest incidence of reported skin conditions. Table 34-5 shows data for rates of skin diseases or disorders in 2015 by industry division. These data indicate that agriculture, forestry, fishing, and hunting carry the highest risks with an incidence rate of 10 per 10,000 full-time workers. The incidence for the goods-producing sector overall is 3.3 per 10,000, higher than the rate for service sector workers. In the service sector, the education and health services division has the highest rate of skin diseases. This is due to the high rate of skin disorders among workers in nursing care facilities (10.4 per 10,000) and assisted living facilities (9.4 per 10,000).

Occupational toxicants may induce diseases in a variety of body sites distant from the lung or skin. These include tumors arising in the liver, bladder, gastrointestinal tract, or hematopoietic system and are attributable to a variety of chemical classes. Further discussion of other occupational diseases and the toxicants listed in Table 34-2 can be found in the relevant chapters in this book.

Nervous system damage can be central, peripheral, or both. It may be acute, as with some organophosphate exposures, or chronic, as with organomercury poisoning or acrylamide-induced neuropathy. Injury affecting the immune system may arise from the immunosuppressive effects of chemicals such as dioxins or toxic metals. Many occupational diseases of the immune system occur due to hypersensitivity leading to respiratory or dermal allergy or systemic hypersensitivity reactions. Autoimmune syndromes have been associated with occupational exposures to crystalline silica and vinyl chloride.

Occupational diseases of the cardiovascular system include atherosclerosis, a variety of arrhythmias, problems with coronary blood supply, systemic hypotension, and cor pulmonale (right ventricular hypertrophy usually due to pulmonary hypertension as with chronic obstructive pulmonary disease). Liver diseases such as carbon tetrachloride-induced fatty liver and hepatocellular death due to toxic concentrations of acetaminophen have classically been used to illustrate chemical mechanisms of cellular injury leading to organ failure. These are thoroughly discussed elsewhere in this book. Occupational diseases of the reproductive system can be sex- and organ-specific, but several toxicants—including carbon disulfide, lead, and vinyl chloride—may affect both sexes.

Exposures to infectious agents are a part of a variety of occupations (Thorne et al., 2015). Veterinarians, health-care workers, and biomedical researchers studying infectious agents have exposures that are largely known and infection control strategies can limit their risks. For others, such as farmers and foresters, specific risks may be less obvious. Zoonotic diseases such as Q-fever, rabies, leptospirosis, and brucellosis may affect abattoir workers, zookeepers, animal handlers, and veterinarians. Foresters, field biologists, and natural resource workers who spend time in wooded areas experience tick- and mosquito-borne illnesses at a higher frequency than that of the general population. These illnesses include the West Nile

Fever and other arboviral encephalitides, chikungunya, Dengue fever, Lyme disease, and ehrlichiosis. Occupational infections may arise as a result of work settings bringing people into close proximity with other people or animals, thus facilitating the transmission of microorganisms. Occupational infectious diseases attributable to the clustering of people affect workers in such facilities as day care centers, schools, health-care settings, correctional facilities, dormitories, military barracks, or shelters for the homeless. Industrial settings can place large numbers of workers in a shared space, leading to increased transmission of diseases. This is especially true for diseases with annual outbreaks, such as influenza. Exposures to chemicals may increase the susceptibility of workers to infection through irritation of mucosa or the pulmonary epithelium or through immunosuppression leading to impaired host defense.

Both industrial and nonindustrial occupational environments may pose occupational hazards due to the presence of chemical or biological agents. Reports of work environments with ineffective ventilation or decreased ventilation rates and increased utilization of synthetic building materials have demonstrated a rise in complaints associated with occupancy in buildings. In some cases, service sector workers in a problem building develop specific clinical conditions with recognized etiology. This is defined as building-related illness. In other cases, symptoms are nonspecific and disappear when the worker leaves the problem building. When this occurs with sufficient prevalence, it is termed *sick building syndrome*. This can arise from volatile and semivolatile chemicals released from office materials, building materials, floor coverings, furniture, cleaning products, and microorganisms. Office buildings and residential settings comprise a complex ecology consisting of people, molds, mites, volatile organic compounds of microbial and nonmicrobial origin, and sometimes plants, pets, cockroaches, and other vermin (Thorne and Heederik, 1999b). Molds, house dust mites, and animal proteins are potent human allergens that can lead to allergy and asthma. Exposure to chemicals and biomolecules such as endotoxin may enhance this process (Douwes et al., 2003). Workers in laboratory animal facilities exhibit a high prevalence of allergy to rodent urinary proteins. In some cases, the occupied space of a building may be clean and dry, but local amplification sites for molds may develop. These may arise in ventilation systems, utility closets, subfloors, or basements that serve as return air plenums, or in local sites of water damage. Such sites can become sources of microorganisms and aeroallergens of sufficient volume to generate significant bioaerosol exposures throughout the environment. Airborne viruses, bacteria, and fungi are responsible for a variety of building-related illnesses arising from organisms that are pathogenic to humans. Nonpathogenic microorganisms may induce symptoms or diseases through inflammatory processes, by stimulating innate or adaptive immune response, or by releasing noxious odors, allergenic compounds, or bioactive macromolecules. These may combine with industrial chemicals released into the air to create complex exposure environments.

TOXICOLOGIC EVALUATION OF OCCUPATIONAL AGENTS

Evaluation of Occupational Risks

In most instances of prolonged exposure to low levels of chemicals, there is a continuum between being healthy and being ill. The exposures may impart biochemical or functional changes that are without signs or symptoms, subclinical changes, or in cases of more significant toxicity, manifest as clinical disease. The health significance of the identified changes resulting from exposure to a particular agent must be assessed in order to determine which effects are adverse. Following this assessment, one must consider the interindividual variability or susceptibility factors that influence the risks. There is no single dose–effect relationship but a distribution of responses. Therefore, in order to recommend an acceptable exposure level to an industrial chemical, one must attempt to define the risk associated with adverse effects in the most sensitive populations exposed. It then remains to be determined what proportion of exposed subjects may still develop an adverse effect at the proposed acceptable exposure level. This acceptable risk level will vary according to a value judgment of the severity, permanence, and equity of the potential adverse effects and the characteristics of the most susceptible population. Clearly, inhibition of an enzyme without functional consequences will be viewed as more acceptable than a chronic non-fatal disease and in turn a more serious toxic effect, such as teratogenicity leading to a congenital malformation in the offspring of the exposed individual.

Establishing Causality In complex occupational environments, it may be difficult to establish a causal relationship between a toxic substance and a disease. For this reason a number of systematic approaches have been devised to help define causation. In 1890, Robert Koch proposed postulates for "proving" that a specific organism caused a specific disease. T. M. Rivers extended this approach to viruses in 1937. Sir Austin Bradford Hill suggested epidemiologic criteria for assessing causality in 1965 considering strength, specificity, consistency, temporality, exposure period, exposure gradients, and biological plausibility of the associations. These schema and modern weight-of-evidence determination criteria led to systematized approaches for establishing strength of associations. U.S. EPA criteria for establishing weight-of-evidence are illustrated in Fig. 34-3. Note that extensive study is required to establish a clear causal link between exposure to a toxicant and an adverse health outcome. Fig. 34-4 provides a matrix to evaluate the weight-of-evidence for a causal association between a

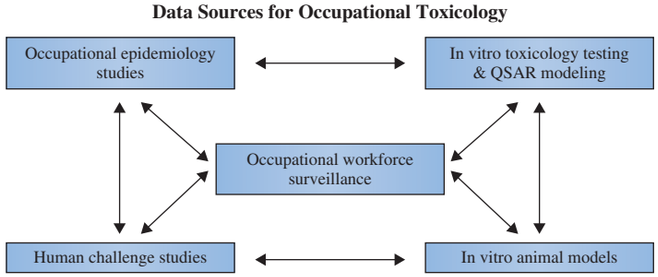

Figure 34-3. *Data sources for occupational toxicology decision making.*

	Assessment of exposure to specific agents	Consideration or control of confounders	Evidence of a dose – response relationship	Consistent results from different studies	Objective clinical data	Endpoints related to human pathology	Appropriate subjects or models
In vitro studies							
Animal studies							
Human challenge studies							
Case studies							
Epidemiology studies							

For each type of study listed in the first column weight the quality of data from existing studies based on the criteria listed in the column headings as follows:

0 No evidence or condition is not met
1 Equivocal evidence or condition is partially met
2 Some evidence or condition is mostly met
3 Clear evidence or condition is convincingly met
4 Squares shown in pink should be left blank

Figure 34-4. *Matrix for assessing the strength of an association between a toxicant and an occupational disease.*

toxicant and an occupational disease (Donham and Thorne, 1994). Evidence from well-conducted in vitro studies, animal toxicology studies, controlled human challenge studies, case reports, and epidemiologic investigations is evaluated with regard to data quality and clarity of evidence in support of the establishment of causality. This evaluation is guided by seven criteria. If a chemical were thoroughly studied in animals, humans, and in vitro studies and it produced clear and convincing evidence of an exposure–response relationship in controlled studies that used appropriate models and relevant endpoints, it would constitute compelling evidence of a causal relationship between that chemical and that disease. Fig. 34-3 reminds us that a consortium of study types contributes data used for the evaluation of occupational hazards. These are discussed below.

In Vitro Assays A number of useful in vitro assays have been developed over the past several decades in order to provide screening data and, in some cases, mechanistic insight without the need or expense of exposing animal or human subjects. While at this time there are few validated methods to determine complex toxicologic responses such as pulmonary hypersensitivity or peripheral neuropathy, the U.S. Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) lists recommended test method protocols for acute systemic toxicity, endocrine disruptors, eye corrosion and irritation, pyrogenicity, and skin sensitization (ICCVAM, 2017). Examples include the Direct Peptide Reactivity assay (OECD TG 442C) and the ARE-Nrf2 Luciferase (KeratinoSens) assay (OECD TG 442D) for predicting skin sensitizers. These methods were approved initially by the European Centre for the Validation of Alternative Methods (ECVAM) and were then accepted by the 32-nation Organization of Economic Cooperation and Development (OECD). Another example is the Bovine Corneal Opacity and Permeability (BCOP) test used to assess the potential for chemicals and consumer products to induce eye injuries (OECD TG 437). In addition, quantitative structure–activity relationships can help suggest potential toxicologic effects for an unstudied compound if structurally similar compounds have been evaluated.

Animal Toxicology Studies Animal toxicology studies serve an important function in terms of identifying adverse effects, providing mechanistic data, establishing dose–response relationships, and aiding the process of establishing standards. Because animal studies can be conducted before there is any human exposure, these studies play an important role in hazard identification and prevention of human disease. There are numerous animal models for occupational injury and illness; these are described throughout this textbook in the context of the affected organ system and the classes of toxicants. Generation of animal toxicology data to predict health effects in workers is a central function of experimental toxicologists.

Toxicologic investigations using animals often serve to establish a tentative acceptable exposure level. Other important information that may also be derived from these investigations concerns the relationships between the metabolic handling of the chemical and its interactions with target molecules (mechanism of action), identification of methods for biological monitoring of exposure and early health effects, and identification of preexisting pathologic states that may increase susceptibility to the chemical. However, animal testing can provide only an estimate of the toxicity of a chemical for humans. Animals do not always respond to a chemical exposure in the same way as humans. For instance, there are very significant species and strain differences in responsiveness to aryl hydrocarbon receptor agonists such as polychlorinated dibenzo-*p*-dioxins (Abnet et al., 1999; Boverhof et al., 2006). In some instances, interspecies differences in metabolism or mechanism of action cause certain chemicals to induce cancer in rodents but not in humans. One such example is kidney cancer, attributable to the accumulation of a rat-specific protein (α_{2u}-globulin) in proximal tubular cells, and produced in male rats chronically exposed to unleaded gasoline (Hard et al., 1993). There are a few compounds for which predictive animal models have not been found.

Human Challenge Studies Controlled human challenge studies, or clinical exposure studies, are a useful approach for verifying findings from animal toxicology studies in humans and for establishing whether biotransformation pathways in the animal models represent those in exposed humans. Human challenge studies with occupational toxicants are usually designed to answer very specific questions regarding rates of uptake, biotransformation pathways, the time course of metabolite excretion during and after exposure, evaluation of the threshold concentration for sensory responses (odor, irritation of the nasal mucosa, etc.), and acute effects of toxicant exposure on perception, vigilance, and lung, cardiac, or neurobehavioral function. Human challenge studies help to establish biomarkers of exposure. For reversible conditions, they can be useful for testing therapeutic options. They may also be useful for investigating bronchial hyperresponsiveness to inhaled agents. Extreme caution must be exercised to ensure the safety of research subjects and the scientific benefits must be balanced against the risks to participants (National Academies of Sciences, Engineering, and Medicine, 2017). Idiosyncratic responses can cause a subject to be exceptionally sensitive. For inhalation studies, equipment malfunction can result in overexposure, so real-time exposure monitoring is a necessity. In the past 25 years, there have been several serious injuries and fatalities associated with human challenge studies. These have been attributed to hypersensitivity reactions and generally used mock workplace simulations without rigorous control and monitoring of exposures, as is the current standard of practice. Thus, such studies should be undertaken only when the required data cannot be obtained through other means and under circumstances in which the risk for volunteers can reasonably be estimated as negligible.

Case Reports When new toxicants, new combinations of toxicants, or changes in process conditions occur in the workplace, a case or outbreak of cases can occur. These may be identified through workplace surveillance systems, OSHA 300 logs, or through workers associating their disease with workplace exposures. In some cases, the problem is identified quickly and resolved, while others take years to resolve. These are often published as case reports and may give rise to animal or epidemiologic studies. Cases of hypersensitivity pneumonitis among machinists exposed to metalworking fluids contaminated with mycobacteria is one example (Weiss et al., 2002; Thorne et al., 2006). Another example is diacetyl-induced bronchiolitis obliterans that was first recognized in workers manufacturing artificially flavored microwave popcorn (Kreiss et al., 2002). NIOSH has a Health Hazard Evaluation (HHE) program in place in which employees or their authorized representatives (i.e., union officials) or employers at a job site can request an investigation to evaluate a potentially hazardous situation (NIOSH, 2017b). This program issues HHE reports to disseminate information regarding the hazard. NIOSH also publishes NIOSH Alerts, Criteria Documents, Fatal Assessment and Control Evaluation Reports, and Current Intelligence Bulletins. It also publishes Joint Occupational Health Documents with similar entities in foreign governments. While useful for hazard identification and mitigation, case reports and HHE reports generally do not establish incidence or prevalence of diseases associated with an occupational hazard.

Epidemiology Studies Epidemiology studies help to unravel the associations between occupational diseases, exposures, and personal risk factors. Exposure may be characterized using a surrogate measure such as job classification or via questionnaire, or more directly through exposure monitoring or biomonitoring. Adverse effects may be expressed in terms of mortality, incidence, or prevalence of clinical disease, irreversible or reversible functional changes, or critical biological changes.

Several types of epidemiologic studies are used to gather data on the association of workplace exposures with human disease. Cross-sectional studies compare disease prevalence or health status between groups of workers classified according to job title, work site, or exposure status. Cohort studies compare exposed workers versus unexposed or less exposed workers either prospectively or retrospectively in order to associate the occurrence of disease with exposure. Because many occupational diseases have a long induction period or occur only rarely, prospective cohort studies may require a long time and need a large number of subjects to establish significant findings. Retrospective cohort studies can resolve the latency problem but require that relevant exposure data have been collected over time. In the absence of measured exposures, job titles, tasks routinely performed, and years of employment may allow categorical exposure classification (e.g., low, medium, and high). Exposure misclassification is frequently a problem in retrospective studies that reduces the likelihood of associating a disease with a particular exposure.

Case–control studies are useful for investigating rare diseases or diseases with long induction periods. As the name suggests, case–control studies compare workers with disease to workers without disease with regard to their past exposure intensity, frequency, and duration, plus other postulated risk factors. In some instances where the exposure–disease relationship is not understood, it may be difficult to identify an appropriate control group. Case–control studies are strongest when accompanied by a rich data set of measured exposures to the candidate causative agents spanning the relevant exposure period. If exposure history is assessed by questionnaire after workers have developed adverse health effects, there arises the potential for recall bias in which those with disease may recall past exposures differently than those who are free of disease. Error can also arise due to selection bias if those who agree to participate in the study are not representative of the population of interest.

Characteristics of observational epidemiology studies are listed in Table 34-7. Occupational epidemiology studies assess relationships between exposures and human health outcomes and, therefore, are particularly useful for risk assessment. Confounding may arise due to exposures of risk factors not associated with the work environment.

Because measures of effect may be subtle and may overlay a background level of incidence, results generally require sophisticated statistical comparisons between a group of exposed workers and a similar group of workers without the exposure of interest. Ideally, the group of unexposed workers should be matched on variables such as age, race, gender, socioeconomic status, and smoking habits. They should also undergo the same standardized clinical, biological, or physiologic evaluation at the same time as the exposed group. Comparison with the general population is ill-advised because an employed population is a highly selected group and may have a higher degree of physical fitness, called the healthy worker effect. Because occupational epidemiologic studies often last for several years, all methods of investigation—such as questionnaires, measurement instruments, and analytic techniques—must be validated and standardized before the start of the study. If results will be compared to prior or contemporaneous studies, the same questionnaires should be used. The number of subjects under study should be chosen based on a sample size calculation to be able to detect a difference between exposed and unexposed subjects (should there be a difference) and should take into account labor turnover and those declining participation in any aspects of the study. If exposures are high enough to induce an adverse effect, it is expected that

these studies may permit establishment of the relationship between integrated exposure (intensity × time) and frequency of abnormal results and, consequently, a redefinition of the OEL.

In most cases, occupational epidemiologic studies encompass the collection of samples from the subjects or data obtained through interaction with the subjects. Because this often includes identifiable private information, the confidentiality of the data must be protected. U.S., EU, and international laws require that subjects must always have the right to refuse participation and investigators must have written consent from a duly informed participant obtained without coercion.

Animal Toxicology Testing for Establishing Acceptable Levels of Exposure

It is evident that certainty as to the complete safety of a chemical can never be obtained, regardless of the extent of toxicologic investigations performed on animals. Nevertheless, animal studies provide valuable data from which to estimate the level of exposure at which the risk of health impairment is acceptable. Table 34-7 compares the information gained from animal studies to epidemiology studies. To the extent possible, animal studies should employ species for which the metabolic pathways and disease processes reflect those of humans. Guidelines and protocols for assessing experimentally the toxicologic hazards of chemicals have been formulated by various national and international agencies. These tests include local and systemic acute toxicity tests, tests of toxicity following repeated exposure, investigations of metabolism and mechanism of action, short-term tests for detecting potential mutagens and carcinogens, studies of effect on reproduction and of teratogenic activity, chronic studies to detect carcinogenesis and other long-term effects, interaction studies, tests for immunosuppression, and dermal and pulmonary hypersensitivity tests. The need for performing these testing protocols should be carefully evaluated for the inclusion of any occupational toxicant to which workers will be exposed. In selecting the studies most appropriate for safety evaluation, the toxicologist should be guided by an understanding of the following:

- Physicochemical properties of the chemical
- Potential for the generation of toxic derivatives when the chemical is submitted to heat, pH changes, and UV light
- Conditions of use and route of exposure
- Type of exposure (continuous, intermittent, or incidental)
- Degree of exposure

Toxicologic information already available on other chemicals with similar chemical structure and reactive chemical groups can suggest potential hazards and reactivity.

Conclusions drawn from any toxicologic investigation are useful only if the composition and physical state of the tested preparation is known. This would include the nature and concentration of impurities or degradation products, speciation of inorganic

Table 34-7

Comparison of Epidemiologic Studies and Experimental Exposure Studies

	OBSERVATIONAL EPIDEMIOLOGIC STUDIES	EXPERIMENTAL ANIMAL EXPOSURE STUDIES
Toxicant exposure	Reflects true exposure among population at risk	Controlled to represent major toxicant of interest
Character	Complex and variable in space and time	Usually one or two test compounds
	May include nonoccupational exposures to toxicant or related compounds	May not reflect complexity of human exposures
Frequency and duration	Work day, work week, and years in that job may be task specific	Acute, subacute, subchronic, chronic
Exposure route	Inhalation, ingestion, percutaneous, or a combination	Injection, inhalation, oral, or dermal; rarely a combination by design
Appropriateness of dose	Reflect the actual range of exposure	Often doses studied are far higher than human exposures
Assessment	Environmental sampling or measurement of biomarkers	Measurement of administered dose with or without measurement of biomarkers
	May be retrospective and based on employer records, group-based approaches, or questionnaires	Sampling of exposure chamber air for inhalation studies
Species considerations	Humans—cohorts or cases and controls	Laboratory animals, usually inbred strains of mice or rats
	Must protect the safety and confidentiality of subjects	Must ensure proper care and use of animals
Representativeness	May exist a selection bias such that the study population may not represent the occupational work force	Experimental animal species may not represent humans
Relevance to human health	Directly relevant if appropriate outcomes are studied	Relevant if species differences are known
		Of limited relevance if species or strain effects on absorption, distribution, metabolism, and disease are unknown
Analytical challenges	Selection bias, misclassification, and confounding in characterization of outcomes	Control of genetics, feeding, and housing between exposed and control groups
	Within- and between-subject variance may be high	Low variance in outcomes

compounds, characterization of physicochemical properties for inhaled materials, and characterization of the vehicle (the carrier, diluent, or excipient of the toxicant). Sensitive and specific methods of analysis of the chemical in solution, air, and biological material should also be available. The assessment of the toxicity of malathion illustrates this point. Malathion is an organophosphate insecticide that normally has relatively low human toxicity. This pesticide was responsible for an episode of mass poisoning among malaria workers in Pakistan because the specific product contained impurities (mainly isomalathion) capable of inhibiting tissue and plasma carboxyesterases (Aldridge et al., 1979) and inactivating acetylcholinesterase via formation of adducts (Doorn et al., 2003). The toxicity evaluation for malathion had not anticipated isomalathion coexposure. A recent study evaluated the pulmonary toxicity of inhaled aluminum nanowhiskers (Adamčaková-Dodd et al., 2012). The manufacturer of this material stated they were Al_2O_3 whiskers. Careful physicochemical analysis prior to toxicity evaluation using X-ray photoelectron spectroscopy and transmission electron microscopy revealed they were actually mixed phase aluminum hydroxy structures containing $Al(OH)_3$ and γ-AlOOH. Further, the whiskers were 100 to 400 nm in length, considerably shorter than the 2800 nm length claimed by the manufacturer.

The duration of tests necessary to establish an acceptable level for occupational exposure is primarily a function of the type of toxic action suspected. It is generally recognized that for systemically acting chemicals, subacute and short-term toxicity studies are usually insufficient for proposing OELs. Subacute and short-term toxicity tests are usually performed to find out whether the compound exhibits immunotoxic properties and cumulative characteristics. They also aid in the selection of the doses for long-term-exposure studies and the kind of tests that may be most informative when applied during long-term exposures. A number of studies have drawn attention to the fact that the reproductive system may also be the target organ of industrial chemicals (e.g., glycol ethers, styrene, lead, dibromochloropropane). Thus, studies designed to evaluate reproductive effects and teratogenicity should also be considered during routine toxicologic testing of occupational toxicants.

Information derived from exposure routes similar to those experienced by workers is clearly the most relevant. For airborne pollutants, inhalation exposure studies provide the basic data on which provisional OELs are based. Experimental methodology is much more complicated for inhalation studies than for oral administration experiments and requires more specialized equipment and expertise. For example, in the case of exposure to an aerosol, particle size distribution must be evaluated and the degree of retention in the respiratory tract of the animal species under study should be established. Ideally, particle size should be selected according to the deposition pattern of dry or liquid aerosols in the particular animal species used in order to represent human lung deposition with occupational exposures. Particle deposition and retention curves have been published for human, monkey, dog, rabbit, guinea pig, rat, and mouse (Schlesinger, 1985; Hsieh et al., 1999; Schroeter et al., 2013; Asgharian et al., 2014, 2016). It should also be kept in mind that the concentration of the material in the air and the duration of exposure do not give a direct estimate of the dose, because retained dose is also dependent on the minute volume and the proportion of inhaled particles retained. Measurement of pulmonary dust retention following exposure to a radiolabeled or fluorescently tagged test aerosol should be performed prior to conducting acute, subchronic, or chronic studies. This allows one to assess deposition and determine whether the selected levels of exposure may overwhelm pulmonary clearance mechanisms (ILSI, 2000; Oberdörster, 2002).

The choice of studies to perform and their routes of administration must be evaluated scientifically for each toxicant. Important considerations include its target sites and mechanism of action, metabolism, the nature of its adverse effects, and how workers are exposed to the toxicant. The morphologic, physiologic, and biological parameters that are usually evaluated, either at regular intervals in the course of the exposure period or at its termination, are described elsewhere in this book. Investigations that can make use of specific physiologic or biochemical tests, based on the knowledge of the principal target organ or function, produce highly valuable information and increase confidence in the OEL derived from them.

Worker Health Surveillance

The primary objective of worker health surveillance programs is to provide both periodic screening of general health and wellness plus health and exposure monitoring tailored to recognized hazards of the workplace. The monitoring of exposures to toxicants in the workplace may play an important role in detecting excessive exposures before the occurrence of significant biological disturbances and health impairment. A scheme for biological monitoring of exposure and of early biological effects is possible only when sufficient toxicologic information has been gathered from in vitro, animal, or human studies on the mechanism of action and the metabolism of xenobiotics to which workers are exposed. When a new chemical is being used on a large scale, the careful clinical surveillance of workers and monitoring of workplaces should be instituted in order to address three aims: (1) to identify overexposure or adverse effects on the health of the workers and quickly intervene, (2) to evaluate the validity of an existing or proposed OEL, and (3) to test the validity of a proposed method for biological monitoring.

Evaluation of the validity of the proposed OEL derived from animal experiments through workplace surveillance is the major aim because studies and observations on humans are the final basis for deciding whether an OEL set originally on the basis of animal toxicity testing is truly acceptable as one that will not produce excess health risks. This means that sensitive clinical, biochemical, physiologic, or behavioral tests for detecting an adverse effect of a toxicant should ideally be performed on the workers concurrent with exposure assessment. It is helpful if health surveillance programs can include the same biomarkers as used in prior animal or human exposure studies. Occupational toxicologists and occupational physicians cannot rely solely on the standard diagnostic tools used in clinical medicine, as they were established primarily to reveal advanced pathologic states and not to detect early adverse effects at a stage when they are still reversible. For example, the measurement of serum creatinine is still a widely used clinical test for assessing renal integrity; yet it is known that the glomerular filtration rate of the kidney must be reduced by more than 50% before serum creatinine rises significantly.

The main limitation of current OELs or BEIs is that some are based on limited experimental data or clinical studies in which only late effects have been investigated and correlated with past exposure. Furthermore, several BEIs are derived from the study of external–internal exposure relationships and not from relationships between internal dose and early adverse effects. The validity of an OEL is much stronger if it is based on the study of dose–response relationships in which the dose is expressed in terms of the cumulative target dose and the monitored effect reflects a critical biological event. However, for some chemicals and some adverse effects (e.g., induction of hypersensitivity and possibly genotoxic

effects), the frequency of peak exposure may be more important for health risk assessment than the integrated dose. For example, long-term low-level exposures to commercial enzymes rarely induce sensitization. However, a single exposure to a high concentration can produce hypersensitivity and occupational asthma.

In cases where a surveillance program was not instituted before the introduction of a new chemical, it is more difficult to establish the efficacy of the OEL. In this situation, evaluation depends on retrospective cohort studies or case–control studies on workers who have already sustained exposure. Evaluation of a "no observed adverse effect level" (NOAEL) is difficult because information on past exposures is often incomplete and frank effects are generally the focus of retrospective or case–control studies. Provided that a satisfactory assessment of past exposure is possible, cross-sectional studies that rely on preclinical signs of toxicity may, to a certain extent, overcome these difficulties. Whether or not clinical investigations are planned from the introduction of a new chemical or process, it is essential to keep standardized records of occupational histories and exposure. The need may arise for mortality or case history studies in order to answer an urgent question on a suspected risk.

Careful investigation of overexposures resulting from specific incidents such as containment breaches, chemical spills, or vessel or pipe ruptures can provide useful information. Although such observations are usually not helpful for determining the NOAEL in humans, they may indicate whether human symptomatology is similar to that found in animals and may suggest functional or biological tests that might prove useful for routine monitoring of exposed workers.

Linkage of Animal Studies and Epidemiologic Studies

In the field of occupational toxicology, perhaps more than in other areas of toxicology, cooperation between those conducting animal studies and studies of workers is helpful for examining risks associated with overexposure to chemicals and other toxicants. A few examples will serve to illustrate the complementarity of these disciplines.

Several occupational carcinogens have been identified clearly through combined epidemiologic and experimental approaches. For example, the carcinogenicity of vinyl chloride was first demonstrated in rats (Viola et al., 1971), and a few years later, epidemiologic studies confirmed the same carcinogenic risk for humans (Creech and Johnson, 1974; Monson et al., 1974). This observation stimulated several investigations on the metabolism of vinyl chloride in animals and on its mutagenic activity in in vitro systems. Identification of vinyl chloride metabolites led to the conclusion that there is microsomal oxidation leading to the formation of an epoxide derivative, which acts as a proximate carcinogen (ATSDR, 2006). This finding triggered further studies on the biotransformation of structurally related halogenated ethylenes, such as vinyl bromide, vinylidene chloride, 1,2-dichloroethene, trichloroethylene, and perchloroethylene. Comparison of their oncogenic activity in relation to their metabolism suggested that an interplay between the stability and reactivity in reaching the DNA target and reacting with it after being formed would determine their genotoxic risk. It is now recognized that vinyl chloride is metabolized to 2-chloroethylene oxide which rearranges to 2-chloroacetaldehyde and produces promutagenic etheno-DNA adducts including etheno-guanine, etheno-cytosine, and lesser amounts of etheno-adenine (Bolt, 2005; ATSDR, 2006; NTP, 2016).

1,3-Butadiene is a known human carcinogen with more than 75% of its use in the manufacture of synthetic rubber products. Experimental studies in rats and mice demonstrated carcinogenicity, with mice being particularly sensitive. Subsequent to these findings, 1,3-butadiene was shown to follow the same metabolic pathway in humans as in rats and mice, forming mutagenic and carcinogenic epoxides. That led to cohort and case–control studies establishing 1,3-butadiene as a human carcinogen (ATSDR, 2009; NTP, 2016). More recent studies have considered the relative importance of the metabolic pathway leading to the formation of the reactive metabolites, 3,4-epoxy-1-butene, 1,2:3,4-diepoxybutane, and 3,4-epoxy-1,2-diol that react with DNA and with nuclear proteins. Under the assumption of a genotoxic mechanism and cross-species comparisons of DNA binding, these data facilitate a more informed cancer risk assessment. In vitro studies showed that human lymphocytes were less sensitive to 1,2:3,4-diepoxybutane-induced chromosomal aberrations than mouse or rat cells (ATSDR, 2009). In vivo studies revealed a higher rate of formation of epoxides in mice than rats. Inhaled 1,3-butadiene produced N7-guanine DNA adducts in lung tissue due to 3,4-epoxy-1,2-diol (Koivisto and Peltonen, 2001) and 1,2:3,4-diepoxybutane (Goggin et al., 2009). These cross links were more prevalent in mice than rats and in females than males which agreed with the enhanced susceptibility to cancers of female mice. On this basis, rats were judged to be a more predictive species than mice for human risk assessment. This work illustrates that the measurement of DNA adducts is a sensitive method for monitoring 1,3-butadiene metabolism via the epoxide-forming pathway in workers.

In 1973, an outbreak of peripheral neuropathy occurred in workers exposed to the solvent methyl butyl ketone (2-hexanone, MBK) (McDonough, 1974; Allen et al., 1975). The same lesion was reproduced in animals (Mendell et al., 1974; Spencer et al., 1975). Biotransformation studies were then undertaken in rats and guinea pigs and some MBK metabolites (2,5-hexanedione, 5-hydroxy-2-hexanone) were also found to possess neurotoxic activity (Spencer and Schaumburg, 1975; DiVincenzo et al., 1977). Similar oxidation products are formed from *n*-hexane, the neurotoxicity of which is probably due to the same active metabolite as that produced from MBK. Because methyl ethyl ketone (MEK) cannot give rise to 2,5-hexanedione, it was suggested as a replacement solvent. Subsequent work demonstrated the potentiation of neurotoxic effects of *n*-hexane upon coexposure with MEK (Yu et al., 2002). Nevertheless, MEK remains a much less toxic solvent than MBK.

These examples demonstrate that studies of the metabolic handling of occupational toxicants in animals are instrumental in the characterization of reactive intermediates and may suggest unsuspected risks or indicate new methods of biological monitoring. Conversely, clinical observations of workers may stimulate studies of the metabolism or the mechanism of toxicity of a toxicant in animals, thereby revealing the health significance of a biological disturbance.

Arsenic is one of the very few compounds for which there are limited data of predictive value from animal studies to human health effects. It has been used as a medicine since the time of Hippocrates. Initially used to treat ulcers, arsenicals achieved notoriety as medicinals for a wide variety of ailments, and then, in the first half of the 20th century, for the treatment of syphilis and parasites. Many foods and beverages contaminated with arsenic have been associated with accidental and intentional poisonings. Inorganic pentavalent arsenic (arsenate) is readily absorbed across tissues and converted to the trivalent form (arsenite). This is then methylated to form monomethyl arsenic acid and dimethylarsenic acid (DMA) (ATSDR, 2007). These are primarily transported in the blood bound to sulfhydryl groups in proteins. The half-life in humans for arsenic compounds is 2 to 4 days and the major excretion is via the urine.

Inorganic arsenic was first noted as a human carcinogen by Hutchinson in 1887 (Hutchinson, 1887). Epidemiologic studies led to classification of arsenic by the IARC as a skin and lung carcinogen in 1980 (IARC, 1980). Since then, studies among occupationally exposed populations and populations with high arsenic in their drinking water have shown conclusively that arsenic causes human cancers of the skin, lung, bladder, kidney, liver, nasal tissue, and prostate. There is also evidence for arsenic-associated cutaneous effects, cardiovascular and cerebrovascular disease, diabetes mellitus, and adverse reproductive outcomes (EPA, 2000; WHO, 2001).

A large number of carefully executed cancer bioassays in mice, rats, beagles, and monkeys performed using sodium arsenate, sodium arsenite, lead arsenite, arsenic trioxide, and DMA were uniformly negative for cancer. A number of subsequent studies that tested for tumor-promotion activity following dosing with recognized tumor initiators also yielded negative results. The 2007 ATSDR Toxicological Profile for arsenic stated, "First and most importantly, no animal model exists for the health effect of greatest concern for human exposure: carcinogenicity in skin and other organs after oral exposure" (ATSDR, 2007). Studies since about 2000, using organic arsenicals, susceptible transgenic mice, high-dose in utero exposures, or administration of a co-carcinogen, have yielded lung adenomas and adenocarcinomas in mice and rats (Shen et al., 2003, 2007; Cui et al., 2006; Hughes, 2006). However, years of negative studies in standard animal carcinogenicity screens were problematic in the face of unquestionable oncogenic activity in humans.

The examples above demonstrate that the occupational toxicologist cannot rely solely on animal or epidemiologic studies. A combined approach is necessary in order to identify, elucidate, and prioritize risks and to develop interventions and techniques for worker health surveillance.

EXPOSURE MONITORING

Two important applications of occupational toxicologic investigations are compared below: environmental monitoring and biological monitoring. As described above under "Occupational Health Standards," both are important in worker health surveillance and are essential elements of toxicology studies with dosing via the inhalation or dermal routes.

Environmental Monitoring for Exposure Assessment

An important objective of experimental and clinical investigations in occupational toxicology is the proposal of safe levels of exposure. OELs must be reevaluated at regular intervals as new information on the toxicity of industrial chemicals develops. Adherence to OELs may not protect everyone and, therefore, cannot supplant close medical surveillance of workers. Various private and official institutions regularly review the toxicologic information on chemicals in order to propose or update permissible levels of exposure. These include governmental and professional organizations worldwide. A critical element of establishing OELs is the accurate assessment of exposure. Methodology for exposure assessment must be specifically tailored to the agent under study and the environment in which it appears. To assess airborne exposures for compliance purposes, personal samples taken in the breathing zone are generally used. In a few specific environments, area samples form the basis of an exposure standard (e.g., the OSHA standard for exposure to raw cotton dust specifies use of the vertical elutriator or an equivalent method). Occupational environmental surveys may employ area sampling to determine areas with higher or lower toxicant concentrations. However, concentrations determined from personal samples typically exceed area concentrations, depending on the work practices and environmental controls. For example, geometric mean concentrations of inhalable dust assessed from 159 personal samples in dairy barns were 1.78 mg/m^3, compared with 0.74 mg/m^3 for 252 area samples collected simultaneously in two locations in the same barns (Kullman et al., 1998). Thus, in this environment, area sampling alone would underestimate personal exposures by a factor of 2.4.

Repeated random sampling is theoretically the best approach to developing unbiased measures of exposure. However, this is rarely the approach that is taken. Variability in exposure, especially variability over time, is often large; therefore, a considerable number of repeated measurements are needed to obtain an accurate proxy of the true exposure. When the number of repeats is insufficient, the slope of the exposure–response relationship will be biased, usually leading to considerable underestimation of the relationship (Heederik and Attfield, 2000). Studies have demonstrated that approaches assessing exposures to groups rather than to individuals are more efficient in terms of measurement effort for obtaining a desired level of accuracy (Vermeulen and Kromhout, 2005). In a group-based approach, workers are grouped by job title, task performed, or through exposure modeling studies to elucidate determinants of exposure, and the group mean is used as the average exposure for each worker (Kromhout et al., 1996). Further statistical modeling of the exposure data can reduce problems of bias and large temporal and spatial variability (Preller et al., 1995; Tielemans et al., 1998). Whereas this approach is gaining acceptance among occupational epidemiologists for evaluating exposure–response data and assessing risks, it is not accepted for compliance monitoring.

Although one cannot assess dose directly through exposure monitoring, it does have several distinct advantages over biomonitoring. Exposure monitoring allows one to quantify workplace exposure by route through selective air monitoring in the breathing zone of the worker and dermal dosimetry using absorptive material affixed to the workers' skin or clothing. Biomonitoring generally does not provide route-specific exposure data. Environmental monitoring techniques are generally less expensive and less invasive than techniques involving the collection and analysis of biological samples such as blood or urine. Thus, a larger population of workers can be studied for the same amount of money. New personal sampling devices incorporate GPS, accelerometers, and smartphone technology to provide enhanced data on location and activity. Workers are accustomed to wearing personal samplers for exposure assessment and are generally quite willing to do so. However, they are often unwilling to give a blood or urine sample, fearing that the sample will be surreptitiously used for drug testing, DNA testing, or experimentation. Another benefit of air sampling in the workplace is that spatial, temporal, and work practice associations can be established and can suggest better interventions and engineering controls to reduce exposures. Finally, analytic interferences and variabilities are generally lower with environmental samples than with biological samples.

A fully validated sampling and analysis method requires specification of the sampling methods; sample duration, handling, and storage procedures; the analytic method and measurement technique; the range, precision, accuracy, bias, and limits of detection; quality assurance issues; and known interferences. It is also important to document intralaboratory and interlaboratory variability. Once a standard method is established, it must be closely followed in every detail in order to assure consistency of results.

The development of accurate and precise analytic methods for environmental assessment is an ongoing effort. NIOSH publishes the extensive *NIOSH Manual of Analytical Methods* (NIOSH NMAM, 2017) and these are widely used. The American Society for Testing Materials (ASTM) has also developed a rigorous system for the establishment of methods. It generally requires 5 or more years to establish a new ASTM method for exposure assessment. The International Organization for Standardization (ISO) is a global federation of national standards bodies with 162 member countries. The subcommittee on workplace atmospheres is administered by the American National Standards Institute (ANSI). ISO has completed harmonization on a number of air sampling methods—for example, the determination of the number concentration of airborne inorganic fibers by phase contrast optical microscopy. The American Industrial Hygiene Association (AIHA) and the ACGIH have published compilations with descriptions of analytic devices and methodology (Cohen and McCammon, 2001; Anna, 2010). Methods have also been developed for bioaerosol exposure assessment and these have been reviewed (Thorne and Heederik, 1999a; Heederik et al., 2003; Hess-Kosa, 2011).

Biological Monitoring for Exposure Assessment

Biomonitoring consists of the measurement of toxicants, their metabolites, or molecular signatures of effect in specimens from humans or animals, including urine, blood, feces, exhaled breath, hair, finger or toenails, bronchial lavage, breast milk, and adipose tissue. These may serve as biomarkers of exposure, biological effect, or susceptibility. New technologies are emerging that will allow measurement and monitoring of chemicals in the body and transmission of the data from indwelling biosensors. Biomonitoring data provide a measurement of exposure based upon internalized dose and, thus, account for all exposures by all routes for the assessed analyte.

Depending on the chemical and the analyzed biological material, the term *internalized dose* may have different meanings. The measured biomarker may reflect the amount of chemical absorbed shortly before sample collection, as with the concentration of a solvent in exhaled air or in a blood sample obtained during the work shift. It may reflect exposure during the preceding day, as with the measurement of a metabolite in blood or urine collected after the end of exposure. For toxicants with a long biological half-life, the measured parameter may reflect exposure accumulated over a period of weeks or months as with arsenic in toenails. *Internal dose* may refer to the amount of chemical stored in one or in several body compartments or in the whole body (*the body burden*).

When biological measurements are available to assess the internal dose, they offer important advantages over monitoring the air of the workplace or measuring deposition of chemicals onto dermal patches. The greatest advantage is that the biological measure of exposure is more directly related to the adverse health effects than environmental measurements because it reflects the amount of toxicant absorbed. Therefore, it may offer a better estimate of the risk than can be determined from ambient monitoring. Biological monitoring accounts for uptake by all exposure routes. Many industrial chemicals can enter the organism by absorption through the skin or the gastrointestinal tract as well as the lung. For example, some solvents (e.g., dimethylformamide) and many pesticide formulations exhibit substantial exposure via the dermal route. In these situations, exposures determined through monitoring airborne concentrations alone underestimate true exposure. Monitoring of an early biomarker of effect is useful when the subjects are exposed to a complex mixture and the agents responsible for the effect are unknown or several agents are working in synergy.

Several factors can influence uptake. Personal hygiene habits vary from one person to another, and there is some degree of individual variation in the absorption rate of a chemical through the lungs, skin, or gastrointestinal tract. Use of size-selective air sampling to determine the inhalable or respirable fraction can strengthen the exposure estimate. However, biological factors such as ventilatory parameters can affect the strength of such a correlation since increased workload can markedly increase the respiratory uptake of an airborne toxicant. Because of its ability to encompass and evaluate the overall exposure (whatever the route of entry), biological monitoring can also be used to test the overall efficacy of personal protective equipment such as respirators, gloves, barrier creams, or aprons. Another consideration with biological monitoring is the fact that nonoccupational exposures (through hobbies, residential exposures, dietary habits, smoking, second jobs) may also be expressed in the biological sample. The organism integrates the total external (environmental and occupational) exposure into one internal load. Whereas this is beneficial for worker health and safety, it may be confounding in epidemiologic studies or compliance monitoring. Thus, while biomonitoring is an important exposure measurement tool for health risk assessment, it generally does not allow one to relate sources and levels of exposure to adverse health effects unless the exposures are unique to the workplace (Albertini et al., 2006).

The value of biological monitoring is heightened when the relationships between external exposure, internal dose, and adverse effects are established. Normally, biological monitoring of exposure cannot be used for assessing exposure to substances that exhibit their toxic effects at the sites of first contact and are poorly absorbed. Examples include dermally corrosive compounds and primary lung irritants. In this situation, the only useful relationship is that between external exposure and the intensity of the local effects.

Relationships between air monitoring and biological monitoring may be modified by genetic or external factors that influence the fate of an occupational toxicant in vivo. Metabolic interactions can occur when workers are exposed simultaneously to chemicals that are biotransformed through identical pathways. Exposure to chemicals that modify the activity of the biotransformation enzymes (e.g., microsomal enzyme inducers or inhibitors) may also influence the fate of another compound. Furthermore, metabolic interferences may occur between occupational toxicants and alcohol, tobacco, food additives, prescription drugs, natural product remedies, or recreational drugs. Changes in any of several biological variables (weight, body mass index, pregnancy, diseases, immune status, etc.) may modify the metabolism of an occupational chemical. These factors have to be taken into consideration when the results of biomonitoring are interpreted. Whatever the parameter measured, whether it is the substance itself, its metabolite, or an early biomarker of effect, the test must be sufficiently sensitive and specific to provide meaningful data in the range of workplace exposures.

Some chemicals have a long biological half-life in various body compartments (e.g., lipophilic persistent organic pollutants) and the time of sampling may not be critical. For other chemicals, the time of sampling is critical because, following exposure, the compounds or their metabolites may be rapidly eliminated from the body. In these cases, the biological sample is usually collected during exposure, at the end of the exposure period, or sometimes just before the next work shift. When biological monitoring consists of the sampling and analysis of urine, it is usually performed on "spot" urine specimens or on the first morning void. It is a standard practice for most organic compounds to adjust the results for urine output by expressing the results per gram of creatinine in the urine.

Table 34-8

Control Approaches for Occupational Inhalation Hazards

Change the process to use or produce less hazardous compounds
Automate and enclose the process to isolate the compounds
Incorporate administrative and work practice controls to reduce duration or intensity of exposure
Install or upgrade local exhaust systems and dilution exhaust
Institute a comprehensive program for personal protective equipment use where necessary

Analyses performed on very dilute urine samples are not reliable. The WHO has specified acceptable limits for urine specimens of between 0.3 and 3.0 g/L creatinine or 1.010 to 1.030 specific gravity (ACGIH, 2016). When samples exhibit large interindividual variability or high "background" levels, the interpretation of a single measurement may be difficult. In such cases, it may be useful to analyze biological material collected before and after the exposure period and gauge exposure based upon the cross-shift change.

The majority of BEIs listed by the ACGIH refer to analysis of the parent compound or its phase I metabolite. Analytical advances over the past decade have yielded methods for detecting reactive intermediates of metabolism and macromolecular adducts that may induce mutations or cell cycle disruption. These methods are important for comparing human and animal toxicity data for risk assessment and may help to explain differential responses in animal models and susceptibility in human populations. These methods may also be useful for occupational health surveillance programs.

Environmental monitoring plays an important role in the evaluation and prevention of excessive exposure to toxicants in the workplace. However, the prevention of acute toxic effects on the respiratory tract, skin, or eye mucosa can only be achieved by keeping the concentration of the irritant substance below a toxic level or by eliminating the exposure. Local acute effects of chemicals do not lend themselves to a biological surveillance program. Likewise, biological monitoring is usually not indicated for detecting peak exposure to dangerous chemicals such as arsine (AsH_3), carbon monoxide, or prussic acid (HCN). Furthermore, identification of emission sources and the evaluation of the efficiency of engineering control measures are usually best performed by ambient air analysis. Table 34-8 lists the approaches most useful for controlling inhalation exposures in the workplace. These include process changes, engineering controls, and use of personal protective equipment. It should be emphasized that process changes and application of engineering controls are preferable to reliance on personal protective equipment.

In summary, environmental and biological monitoring should not be regarded as opposites but as complementary elements of an occupational health and safety program. They should be integrated as much as possible to ensure low levels of contaminants and optimal health for workers.

CONCLUSION

The working environment will always have the potential to overexpose workers to toxicants. Recognition of these risks should not wait until epidemiologic studies have uncovered hazardous levels. A combined experimental, clinical, and epidemiologic approach is most effective for evaluating and managing the potential risks. One can then promulgate scientifically based occupational health standards, apply effective workplace controls to ensure adherence to those standards, and institute worker health surveillance programs to identify unexpected effects in susceptible individuals.

WHAT IS REGULATORY TOXICOLOGY?

Regulatory toxicology is a subfield of regulatory science, which addresses the intersection of science with regulation, namely how the science of toxicology is developed, evaluated, and applied in regulatory decision-making. Toxicology is one of the most common fields of scientific knowledge utilized in regulatory science, as regulatory agencies often are required to identify and quantify the health risks of the products and activities they seek to regulate. Regulatory toxicology, which must straddle traditional scientific methodologies with the public policy world of regulation, strains to adhere to the standards of good toxicological science while also providing relevant inputs to decision-making, which often asks questions that science cannot answer completely or with any certainty. It is the tension between these two different worlds of science and policy that raise many of the most important and challenging issues in regulatory toxicology, many of which are addressed in this chapter.

*The author acknowledges and appreciates the work of Professor Richard Merrill, a pioneer in the legal study of regulation, who authored earlier versions of this chapter and upon whose work this chapter builds.

Over the past 50 years, the field of regulatory toxicology has grown enormously as the intersection between regulation and toxicology has expanded dramatically. With the enactment of a series of environmental, health, and safety laws in the United States, Europe, and elsewhere in the 1970s and 1980s, regulatory agencies increasingly rely on toxicological science to identify potential hazards, prioritize chemicals and other potentially toxic substances, and provide the data used for assessing and managing risk. Regulators are not merely consumers of toxicological studies but also help shape toxicology science in important ways. Regulatory programs have provided a major impetus for improvements in toxicology methods, and they have stimulated a demand for toxicology studies that meet various regulatory requirements. Some programs, such as regulatory programs for licensing drugs, devices, food additives, and pesticides, explicitly demand toxicology studies as a condition for marketing products. Other statutory and regulatory requirements, such as the recent program requiring agencies to screen chemicals for their endocrine disruptor capability, or agencies to evaluate the safety of new nanotechnology applications, are a major driver for the development of new types of toxicological assays.

Regulatory agencies have exercised important influence over the design and conduct of toxicology studies. For example, the United States Environmental Protection Agency (EPA) is

empowered by the Toxic Substances Control Act (TSCA) to promulgate standards for different types of toxicology (and other scientific) investigations. Likewise, the U.S. Food and Drug Administration (FDA) has long issued guidelines for laboratory studies submitted in support of food additives and drugs. Both agencies have adopted requirements governing laboratory operations and practice, known as Good Laboratories Practice (GLP). Communication between government officials and laboratory scientists flows in both directions. Government testing standards are influenced strongly by the prevailing consensus among toxicologists, many of whom work in regulatory agencies. Similar standards have been established at the international level through the Organization for Economic Co-operation and Development (OECD).

THE SCIENCE/POLICY INTERFACE IN REGULATORY TOXICOLOGY

There are critical differences between the objectives and methods of science and regulatory policy. Science seeks to understand natural phenomena through objective, empirical, and neutral methodologies, and is cautious, incremental, and evidence-based. In contrast, government regulation seeks to affect human behavior and resolve human disputes; it is episodic, peremptory, and normative, pursuing goals such as human welfare, safety, efficiency, and fairness.

Science is open-ended and can continue to study a problem indefinitely without coming to any final resolution. As the National Research Council noted, "the scientific process of seeking the truth, by design and to its credit, has no natural endpoint" (NRC, 2009). In contrast, regulation usually does not have the luxury of waiting until the science has matured, but rather must come to decisions based on legislative, political, and societal deadlines. This creates two problems. First, finality is essential for regulations, so that regulated entities and other stakeholders have certainty about the applicable regulatory requirements, which often involve significant resources and lead time to achieve compliance. Consequently, regulations are adopted as final decisions, which can only be reconsidered at significant administrative burden. Science meanwhile continues to develop, resulting in regulations that often become increasingly outdated in relationship to constantly evolving scientific data and understanding.

The second problem created by the need to adopt regulations on a set timetable is often that the scientific inputs into that regulatory decision remain uncertain and underdeveloped. This leads to what Alvin Weinberg referred to as the "regulator's dilemma": "the regulator, by law, is expected to regulate even though science can hardly help him; this is the regulator's dilemma" (Weinberg, 1985). Regulatory agencies are therefore required to make numerous assumptions to fill the gaps in the available scientific data (NRC, 1983). This then has the inevitable effect of making agency determinations a mixture of science and policy, which can lead to confusion and obfuscation.

Scientists are often frustrated by the political and administrative requirements (often referred to colloquially as "red tape") associated with regulatory utilization of toxicological data. A regulatory proposal incorporating scientific evidence has to pass through many layers within a regulatory office, including the agency scientists, economists, program officers, office of the general counsel, political appointees, various centers, programs, and offices within the agency that are affected by the proposed decision, external advisory committees, and finally the agency head, subject at every stage to a bevy of internal control requirements and processes. When the agency has finally made its proposed decision, the proposal is often then scrutinized by the Office of Information and Regulatory Affairs (OIRA) in the White House, courts conducting judicial review, Congressional oversight committees, and of course external stakeholders and the media. At every step along this pathway, the scientific findings of the agency are subject to challenge, prodding, and second-guessing.

This elaborate regulatory process has a number of implications. First, regulatory agencies tend to attempt to buttress their regulatory decisions with extensive analytical support. As a comparative study of US and European regulation observed, "American regulators, being more politically exposed than their European counterparts, have a greater need to support their actions through formal analytical arguments. Their demand for expertise necessitates a continuing build-up of technical capabilities and the development of more sophisticated and detailed analytical methodologies. The structure of the American rule-making process subjects the analytical case for regulation to intense political scrutiny. Any weaknesses are quickly exploited, and the uncertainties and shortcomings of the relevant scientific base are readily exposed …" (Brickman et al., 1985). In response to these pressures, regulatory agencies will often compile extensive scientific assessments of the toxicological and other data supporting their regulatory decisions, sometimes thousands of pages in length.

Another consequence of the highly politicized and adversarial nature of regulatory decision-making is that regulatory agencies have an incentive to overstate the scientific basis of their decisions. Although scientific data are a critical input into sound regulatory decision-making, the actual decision of how much protection to provide and which requirements or limits to impose is inevitably a normative policy decision, even if informed by scientific information and knowledge. Yet, agencies receive greater deference from Congress, the White House, reviewing courts, and even the media and public if they justify their decision on scientific rather than policy or normative grounds. Accordingly, regulatory agencies are inclined to give disproportionate weight to scientific arguments and evidence in trying to justify their decisions, a tendency that has been labeled in the literature as the "science charade" (Wagner, 1995).

AN OVERVIEW OF REGULATORY APPROACHES

Different agencies and even different regulatory programs within the same agency use toxicological data in different ways. One important difference relates to the extent of premarket analysis or approval required before a new product may be commercialized. Some products require premarket approval from a regulatory agency (e.g., drugs and medical devices by FDA and pesticides by EPA), other products require only premarket notification to the agency (e.g., new chemical substances), whereas still other products require no premarket activity with a regulatory agency (e.g., foods, cosmetics) before they can be sold commercially. There are also differences in who has the burden of proof to demonstrate safety or hazard. For example, the manufacturer of a new food additive has the burden to demonstrate to the FDA the lack of hazard before humans may be exposed, while laws such as the Occupational Safety and Health Act (1970) put the burden on regulators to show that a substance is hazardous before exposures can be restricted. The approach chosen by Congress for a particular type of product or activity greatly influences an agency's ability to require comprehensive toxicological investigation prior to commercialization.

In determining what level of a substance to allow, regulatory agencies generally use one of three different approaches: (i)

acceptable risk, (ii) balancing, or (iii) feasibility. The determination of which of these three approaches is used for a particular hazard is generally determined by the applicable statutory framework.

Acceptable Risk

This approach determines the level of risk a substance presents, and then seeks to lower that risk (if necessary) to a level that is "acceptable." Because these risk-based programs only consider health evidence, toxicological data play a central role in these regulatory programs. In making the determination of acceptable risk, agencies have traditionally distinguished between carcinogens and noncarcinogens in their approach. For noncarcinogenic chemicals, regulators have generally embraced a standard safety assessment formula, built around the concept of acceptable daily intake (ADI) for the FDA or reference dose (RfD) or reference concentration (RfC) in the case of EPA. These levels are derived by applying a series of safety factors to the lowest "no observed adverse effect level" from animal experiments. Human exposures to a chemical that fall below the resulting ADI, RfD, or RfC are assumed to be "safe" or acceptable. This traditional approach to noncarcinogenic toxicants has not been considered appropriate for carcinogens. Regulators in the United States and many of their counterparts in other countries have operated on the premise that carcinogens as a class cannot be assumed to have "safe" or threshold doses. Furthermore, they have assumed that any chemical shown convincingly in animal studies to cause cancer should be considered a potential human carcinogen. Accordingly, for this group of compounds, regulators have generally assumed that no finite level of human exposure can be considered risk-free. As research has begun to illuminate the different mechanisms by which chemicals may cause cancer, however, regulatory agencies have cautiously accepted the possibility that "safe" thresholds may be established for at least some non-genotoxic carcinogens.

An example of an "acceptable" risk-regulatory program is the national ambient air quality program under the Clean Air Act (CAA). Under this program, EPA must set standards for criteria air pollutants such as particulate matter, ozone, and carbon monoxide that protect against "adverse effects" in the most susceptible subgroup with an adequate margin of safety. EPA may only consider risk data in setting these standards; no consideration of costs or feasibility is permitted (*Whitman v ATA*, 2001). A more stringent form of the acceptable risk approach is a "zero" or "negligible" risk requirement, epitomized by the famous Delaney clause, enacted in 1958 as part of the Food Additives Amendment. The amendment itself requires that any food additive be found "safe" before the FDA may approve its use (Food Additive Amendment, 1958). The Delaney clause stipulated that this finding may not be made for a food additive that has been shown to induce cancer in humans or in experimental animals. In 1996, Congress amended the provisions of the Food, Drug, and Cosmetics Act applicable to pesticide residues in food, revoking the Delaney proviso as it applies to food additives (but not color addictives), and adopting a standard that, though not expressed in these words, is understood to permit a tolerance for a carcinogenic pesticide if the estimated cancer risk is extremely small, on the order of one in one million (Food Quality Protection Act, 1996).

Balancing Approaches

Other regulatory programs require the agency to balance the health benefits of risk reduction against the costs of such reductions. These approaches known as cost-benefit or risk-benefit analysis generally require a quantified estimate of both the health risks and costs associated with various regulatory options, and the agency then chooses the regulatory option that offers the biggest estimated net benefit. Both toxicological and economic data play key roles in these statutory programs for calculating the benefits and costs of regulation, respectively. The original TSCA statute enacted in 1976 is an example of a statute utilizing a balancing approach, requiring EPA to set standards for toxic substances based on a quantified cost-benefit analysis (*Corrosion Proof Fittings v EPA*, 1991). The 2016 amendments to TSCA generally eliminate consideration of costs and other non-risk factors in determining unreasonable exposures, thereby converting TSCA from a cost-benefit to an acceptable risk statute. Pharmaceutical drugs approved by the FDA continue to use a risk-benefit approach, whereby safety is determined by considering whether the health benefits of the drug exceed the health risks associated with the drug.

Feasibility/Best Available Technology

The third major approach requires the agency to reduce exposures to the lowest feasible level, or to require companies to install the best available technology. This approach does not explicitly rely on any health data, and this skirting of the complexities and uncertainties of toxicological evidence is seen by some as a major advantage of this approach. The consequence of ignoring health impacts, though, is that the resulting standards may overprotect or underprotect health. An example of such a feasibility-based approach is the Clean Water Act's effluent standards, which requires dischargers of pollutants to install the best available technology determined to be feasible for that industrial category. A program using a hybrid feasibility/acceptable risk approach is the Occupational Safety and Health Act, which directs the Occupational Safety and Health Administration (OSHA) to set workplace standards for hazardous exposures to the level "which most adequately assures, *to the extent feasible* … that no employee will suffer material impairment of health or functional capacity" (Occupational Safety and Health Act, 1970). This language has been interpreted by OSHA and the courts as requiring the agency to set occupational health standards at the lowest exposure level that is technologically and economically feasible, to the extent necessary to reduce a "significant" risk (*American Textile Manufacturers Institute v Donovan*, 1982).

SPECIFIC REGULATORY PROGRAMS UTILIZING TOXICOLOGICAL DATA

At the federal level, four agencies are chiefly responsible for regulating human exposure to toxic materials: the FDA, EPA, OSHA, and the Consumer Product Safety Commission (CPSC). Together they administer over two-dozen statutes whose primary goal is the protection of health. The statutes administered by these four agencies utilize different regulatory approaches and require divergent safety benchmarks. This diversity has several explanations. The statutes were enacted in different eras. They originated with different political constituencies and remain under their influence. Perhaps most significant, statutory standards often reflect differences in the technical capacity to control different types of exposures, and they embody different Congressional judgments about the economic implications of limiting exposures.

Food and Drug Administration (FDA)

The oldest of the major health regulation laws, the FFD&C Act, was originally enacted in 1906 and, as amended over time, now covers food for humans and animals, human and veterinary drugs, biologics, medical devices, cosmetics, and tobacco products.

Food The initial Food and Drug Act enacted in 1906 prohibited "adulterated" foods that contain "any poisonous or deleterious substance, which may render it injurious to health." This provision, which remains in the statute to date [FFD&C Act § 402(a)], does not require premarket approval of foods and puts the burden of proof on FDA to demonstrate that a food meets the definition of "adulterated."

Congress has since amended the act several times to strengthen the FDA's ability to ensure the safety of foods (FFD&C Act, 1938). The most important of these amendments was the 1958 Food Additives Amendments that require the safety of food additives to be demonstrated prior to marketing (Food Additive Amendments, 1958). The manufacturer of a food additive must submit a petition demonstrating that the substance is "reasonably certain to be safe"; no inquiry into the benefits of an additive is undertaken or authorized (Cooper, 1978). The food additive regulations require that the quantity of the substance added to food does not exceed the amount reasonably required to accomplish its intended physical, nutritive, or other technical effect in food. Two categories of nonnaturally occurring food ingredients were exempted from this food additive requirement: (a) substances generally recognized as safe among experts qualified by scientific training and experience to evaluate safety; and (b) substances that either FDA or the US Department of Agriculture (USDA) had sanctioned for use in food prior to 1958 (so-called "prior sanction" substances).

Separate regulatory standards have been developed for several classes of indirect food constituents. For example, a food-contact substance requires approval as a food additive if, when used as intended, it "may reasonably be expected to become a component of food." In 1997 omnibus legislation that addressed most of FDA's regulatory programs, Congress created a new premarket notification system for food-contact materials that permits the agency to delay introduction if it questions a material's safety, but does not require affirmative agency approval (FDA Modernization Act, 1997).

In 2011, Congress enacted the FDA Food Safety Modernization Act (FSMA, 2011), which seeks to strengthen food safety by shifting the focus of federal regulators from responding to contamination to preventing unsafe foods. The legislation mandates the FDA to establish comprehensive, science-based preventive controls across the food supply, which includes a requirement for food facilities to adopt and implement written preventive control plans, a mandate that FDA establish science-based, minimum standards for the safe production and harvesting of fruits and vegetables, and new authority to prevent intentional contamination of food. The statute also gives FDA enhanced enforcement and inspection authority, authorizes FDA to conduct mandatory recalls of unsafe foods, and new powers to ensure that imported products meet U.S. standards and are safe for U.S. consumers.

Human Drugs and Biologicals Preclinical studies in animals play an important role in the FDA's evaluation of human drugs and biologicals. The current law requires premarket approval, for both safety and efficacy, of all "new" drugs, a category that embraces virtually all prescription drug ingredients introduced since 1938 (Hutt et al., 2007). Premarket approval of drugs for commercial use primarily relies on randomized controlled trials in human subjects to establish safety and efficacy. However, animal and in vitro studies are the primary source of information about a substance's biological effects before human trials are begun, and their results influence not only the decision whether to expose human subjects but also the design of clinical protocols.

The FDA reviews the clinical evidence before authorizing human clinical trials through review of an Investigational New Drug (IND) application. The IND must include (i) preclinical data to permit an assessment as to whether the product is reasonably safe for initial testing in humans, including animal pharmacology and toxicology studies (with the core battery of studies including the assessment of effects on cardiovascular, central nervous, and respiratory systems, as well as acute toxicity, with other types of studies conducted on a case-by-case basis as warranted), in vitro and in silico data, and any previous experience with the drug in humans (often foreign use); (ii) manufacturing information to ensure that the company can adequately produce and supply consistent batches of the drug, including data on the composition, manufacturer, stability, and controls used for manufacturing the drug; and (iii) clinical protocols and investigator information, including detailed protocols for proposed clinical studies, information on the qualifications of clinical investigators, and commitments to obtain informed consent from the research subjects and to obtain review of the study by an institutional review board (IRB).

Once an IND has been approved, the drug sponsor may proceed with human clinical studies consistent with the IND. The drug testing traditionally proceeds in three sequential phases. Phase 1 involves 20 to 100 healthy volunteers or people with the disease/condition and lasts several months, with the objective of evaluating drug safety and dosage. Phase 2 trials involve up to several hundred patients with the disease/condition, and last several months to 2 years, with the purpose of evaluating efficacy and side effects. Finally, at least two Phase 3 trials are required, which involve 300 to 3000 subjects who have the disease or condition, and these trials take 1 to 4 years. In some cases, such as when the FDA grants accelerated approval to a therapeutic, the agency can require a post-marketing study known as a Phase 4 study, to monitor the safety, efficacy, and side effects of the drug in clinical use.

Another category of drugs regulated by FDA is over-the-counter (OTC) drugs, which do not require a prescription. An OTC drug can receive regulatory authorization in two ways. First, the sponsor of an FDA-approved prescription drug can petition the FDA to change the status of the drug to OTC, a process referred to as an "Rx-to-OTC switch," if certain requirements regarding safety, efficacy, risk-benefit ratio, and consumer understanding of labeling can be demonstrated. The second method is the FDA "monograph" program, which consists of criteria for various categories of OTC drugs (e.g., antacid, cough/cold, dandruff shampoo, and sunscreens). A new product that meets the Monograph criteria for the relevant category of OTC drug can be marketed without FDA pre-approval.

Medical Devices In 1976, Congress overhauled the FFD&C Act's requirements for medical devices, providing the FDA major new authority to regulate their testing, marketing, and use. The elaborate new scheme contemplates three tiers of control, the most restrictive of which (class III) is premarket approval similar to that required for new drugs. To obtain FDA premarket approval of a class III device, the sponsor must demonstrate safety and efficacy. The bulk of the data supporting such applications will be derived from clinical studies but also will include toxicology studies of any constituents likely to be absorbed by the patient.

Cosmetics The statutory provisions governing cosmetics do not require premarket approval of any ingredient, or demand that manufacturers test their products for safety, though many manufacturers routinely do so. The basic safety standard for cosmetics is similar to that for food ingredients: no product may be marketed if it contains "a poisonous or deleterious substance, which may render it injurious to health" [FFD&C Act § 601(a)]. The case law establishes that this language, too, bars distribution of a product

that poses any significant risk of more than transitory harm when used as intended, but it places on the FDA the burden of proving a violation (Hutt et al., 2007). The FDA has brought few cases under this standard, in part because acute toxic reactions to cosmetics are readily detected and immediately result in abandonment of the offending ingredient. The FDA encourages cosmetic firms to participate in its Voluntary Cosmetic Registration Program (VCRP), which is an online registration system that cosmetic manufacturers, distributors, and packers can file information on their products that are currently being marketed to consumers in the United States and register their manufacturing and/or packaging facility locations in the VCRP database. The FDA also relies on the Cosmetic Ingredient Review (CIR), a private expert assessment body established in 1976 and operated by the Personal Care Products Council. The CIR appoints an expert panel that conducts safety assessments of cosmetics ingredients that are subject to public review and comment and then published as monographs.

Environmental Protection Agency (EPA)

The EPA is responsible for administering most of the nation's environmental laws, which include protection of both human health and the environment. A comprehensive review of the EPA's numerous programs is not possible here; the following summary focuses on those EPA activities in which toxicology evidence plays a central role: the agency-wide Integrated Risk Information System (IRIS) program, pesticide regulation, regulation of industrial chemicals, regulation of drinking water supplies, hazardous waste control, and regulation of toxic pollutants of water and of air.

IRIS Program EPA's IRIS provides an agency-wide scientific assessment program to evaluate the carcinogenic and noncarcinogenic human health risks of various chemicals. EPA prepares a Toxicological Review for a chemical, which goes through a series of internal and external reviews before being finalized, which is then used to derive an RfD and/or inhalation RfC for noncarcinogenic effects, and a weight-of-evidence determination as well as oral and inhalation unit risks for carcinogenic effects. IRIS values are used to support a variety of agency regulatory programs, including many of those described below. EPA has established IRIS values for over 500 chemical substances. In response to a critical National Research Council study of EPA's IRIS assessment of formaldehyde (NRC, 2011), the EPA has restructured its IRIS process to adopt systematic review methods and information management tools for study selection and analysis, and "data integration" approaches to develop overall hazard findings. In addition, IRIS assessments now derive organ-specific reference values (in addition to overall RfD and RfC values) when health effects data are available. The future of the IRIS program is in question, as both the Trump Administration and Congress are calling for major changes and possible funding cuts to the program.

Pesticides Pesticides are subject to two types of regulation: (i) registration under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA, 1972), which is required for a pesticide to be marketed in the United States; and (ii) tolerance (under the FFD&C Act), which sets the allowable level of pesticide residue in food for human consumption. Pesticide residues on raw agricultural commodities for years were initially regulated by the EPA under a 1954 amendment to the FFD&C Act, which allowed the agency to set tolerance levels based on weighing the potential adverse health effects of residues against the benefits of pesticide uses. If the concentration of a pesticide in a processed food exceeded the established tolerance, or the pesticide was a carcinogen, the Delaney clause prohibited its approval for that use (*Les v Reilly*, 1992). This framework was revised by Congress in 1996 by the Food Quality Protection Act (FQPA) to exempt pesticide residues from the operation of the Delaney clause but also restricted the consideration of pesticide benefits in setting tolerances.

The FQPA integrated the standard for registration and tolerance of a pesticide to require a pesticide to be shown to be safe, a standard defined as "reasonable assurance of no harm" (Food Quality Protection Act, 1996). The 1996 amendments also introduced some additional novel elements to the tolerance process. First, it required EPA to determine the safe level of a pesticide residue in a cumulative context, considering "all anticipated dietary exposures and all other exposures for which there is reliable information" [21 USC § 346a(b)(2)(A)(ii)]. This includes other nonoccupational sources of exposure, including food, drinking water, and residential exposures [21 USC § 346a(b)(2)(D)(vi)]. EPA must also base its safety determination on a consideration of exposures to other pesticides that share the same mechanism of toxicity [21 USC § 346a(b)(2)(C)(i)(III)].

Second, the 1996 FQPA required EPA to give special consideration to the health of infants and children, by ensuring "that there is a reasonable certainty that no harm will result to infants and children from aggregate exposure to the pesticide chemical residue …" [21 USC § 346a(b)(2)(C)(ii)(I)]. To implement this requirement, the statute directs EPA to "use an additional 10-fold margin of safety in assessing the risks to infants and children to take into account potential for pre- and postnatal toxicity and the completeness of the toxicology and exposure databases." EPA can deviate from the 10-fold margin of safety "only if, based on reliable data, the resulting margin would be safe for infants and children" [21 USC § 346a(b)(2)(C)(ii)(I)]. EPA's failure to provide a legally sufficient rationale for not applying the presumptive 10-fold extra safety factor for children has been found to be arbitrary and capricious by reviewing courts (*Northwest Coalition for Alternatives to Pesticides v EPA*, 2008; *NRDC v EPA*, 2011).

Third, EPA must develop a program to test for endocrine disrupting effects of pesticides. There has been a flurry of research over the past couple of decades addressing the identification and mechanisms of toxicity from endocrine-disrupting chemicals (Marty et al., 2011). The FQPA required EPA to "develop a screening program, using appropriate validated test systems and other scientifically relevant information, to determine whether certain substances may have an effect in humans that is similar to an effect produced by a naturally occurring estrogen, or such other endocrine effect as the Administrator may designate" [21 USC § 346a(p)(1)]. Although EPA was required to establish this program by 1999, it did not meet this deadline.

EPA has been moving forward nevertheless and has created an Endocrine Disruptor Screening Program, which involves a two-tier screening and testing process: In Tier 1 testing, EPA seeks to identify chemicals that have the potential to interact with the endocrine system. Tier 1 consists of 11 different assays, which are being applied to 67 pesticide ingredients on EPA's initial list of chemicals to be tested, which was released in 2009. EPA completed this first round of Tier 1 testing in September 2015 with results for 52 chemicals (the other 15 chemicals on the original list were dropped because they are no longer in use). Of these 52 chemicals, 34 were found to have no significant endocrine disruptor activity, while the other 18 were found to have some activity and were selected for Tier 2 testing. EPA finalized in 2013 a second list of 109 additional chemicals to be tested in Tier 1 (of which 2 were subsequently removed from the list in 2014). In Tier 2, EPA will determine the endocrine-related effects caused by each chemical that indicated endocrine disruption activity in Tier 1, and obtain information

about effects at various doses in order to enable risk assessment. The agency finalized three Tier 2 testing guidelines in August 2015 (EPA, 2015a). Also in 2015, EPA published a proposal to allow companies to use high-throughput assays and computational toxicology as an alternative screening method for endocrine disruptors (EPA, 2015b).

After the FQPA of 1996, the pesticide registration process now includes a broader review of the human health impacts from commercial use of the pesticides on applicators and other individuals, as well as effects on the environment. The manufacturer of a pesticide must produce a variety of data from tests done according to EPA guidelines. EPA's test guidelines, most recently revised in 2013, now encompass guidelines for several hundred types of tests recommended for pesticides (40 CFR 158 and 161). These tests evaluate whether a pesticide has the potential to cause adverse effects on humans, wildlife, fish, and plants, as well as possible contamination of surface water or ground water from leaching, runoff, and spray drift. The potential human risks that are evaluated include both acute and chronic toxicity. The EPA then conditions the use of the pesticide on various protections to ensure that the pesticide is used safely, which are summarized on the pesticide label.

The EPA has been engaged in a comprehensive review of previously registered pesticides and "reregistration" of those that meet contemporary standards for marketing for approximately the past three decades. Under this program, many older pesticides have been subjected to comprehensive toxicology testing, including carcinogenicity testing, for the first time, and the results have required modification of the terms of approved use and, in some instances, cancellation for several pesticides. The FQPA required EPA to review the registration ("reregistration") and tolerance of older pesticides. In addition, EPA initiated a new program in 2006 called "registration review" in which it intends to re-evaluate all pesticides every 15 years. Finally, EPA may initiate a "Pesticide Special Review" process whenever it discovers that the use of a registered pesticide may result in unreasonable adverse effects on people or the environment.

Industrial Chemicals The Toxic Substances Control Act (TSCA) was promulgated in 1976 to regulate all chemical substances manufactured or processed in or imported into the United States, except for substances already regulated under other laws (e.g., pesticides, tobacco products, firearms, foods, drugs, and cosmetics). *A chemical substance* is defined broadly as "any organic or inorganic substance of a particular molecular identity." Forty years after the initial adoption of TSCA in 1976, in 2016 the Frank R. Lautenberg Chemical Safety for the 21st-Century Act was signed into law, the first major amendments to the TSCA statute (TSCA, 2016).

As amended, TSCA gives the EPA three main powers. First, the agency is empowered to restrict or even ban the manufacturing, processing, distribution, use, or disposal of a chemical substance when there is a reasonable basis to conclude any such activity poses an "unreasonable risk of injury to health or environment." Prior to the 2016 amendments, the agency was instructed to balance the costs of restricting the substance against the health benefits of the proposed regulation and to choose "the least burdensome requirement" [TSCA § 6]. This trade-off approach to regulation proved a major challenge to the EPA and the agency exercised its regulatory authority under the original section 6 against only a handful of substances, and its most significant regulations, such as its attempted ban on asbestos products, have been struck down by the courts for failing to do an adequate cost-benefit analysis (*Corrosion Proof Fittings v EPA*, 1991). The statute itself imposes restrictions on two types of chemicals: mercury and polychlorinated biphenyls (PCBs).

The 2016 amendments to TSCA seek to rejuvenate section 6. The amended statute deletes the "the least burdensome requirement" provision, and requires EPA to undertake a prioritization process that involves screening existing chemicals based on factors such as hazard, exposure potential, persistence, and bioaccumulation, but without considering cost. Any chemical that is found to "may present an unreasonable risk" based on this screening analysis must be categorized as high priority and is subject to a risk evaluation. The risk evaluation is intended to determine whether a chemical presents an unreasonable risk, without considering costs or other non-risk factors. EPA must then promulgate a risk management standard for any chemical that is found to present an unreasonable risk in the risk evaluation.

The second major authority under TSCA is that if the EPA suspects that a chemical *may* pose an unreasonable risk but lacks sufficient data to take action, TSCA empowers the agency to require testing to develop the necessary data. Similarly, it may order testing if the chemical will be produced in substantial quantities that may enter the environment and/or result in significant human exposure whose effects cannot be predicted on the basis of existing data. In either case, the EPA must consider the "relative costs of the various test protocols and methodologies" and the "reasonably foreseeable availability of the facilities and personnel" needed to perform the tests [TSCA § 4]. The 2016 revisions to the TSCA testing authority require EPA to use tiered testing and screening approaches, and to reduce and replace vertebrate animal testing when this can be scientifically justified.

Finally, to enable the EPA to evaluate chemicals before humans are exposed, TSCA requires the manufacturer of a new chemical substance to notify the agency 90 days prior to production or distribution [TSCA § 5(a)(1)]. The manufacturer's or distributor's notice (called a pre-manufacturing notice or PMN) must include (i) chemical identification, including the Chemical Abstract (CA) name (when available), the chemical formula, and the molecular structure of the substance, and any synonyms, trade names, or generic names for the chemical; (ii) information on the physical properties of the substance; (iii) amounts and identities of any impurities in the chemical substance; (iv) any byproducts that result from the manufacture, processing, use, and disposal of the new chemical substance; (v) production volume for the first 12 months of production and estimate of the maximum production volume for any consecutive 12-month period during the first 3 years of manufacture; (vi) intended use of the substance including the degree of containment; (vii) any information on manufacturing, processing, and use operations involving the new chemical substance or products containing the new substance; (viii) any hazard warning statement, label, material safety data sheet (MSDS), or safety data sheet (SDS) available for the substance; (ix) anticipated environmental release and disposal information; and (x) (optionally), information on pollution prevention and recycling activities involving the new substance. In addition, the manufacturer must submit any hazard, toxicology, or safety data or studies it has on the substance.

Prior to the 2016 amendments, if EPA did not take action within 90 days, the manufacturer may proceed with commercialization of the chemical substance. Under the 2016 amendments, EPA *must* review all new chemicals and significant new uses (SNUs) and must make one of three findings: (1) that the new chemical or SNU presents an unreasonable risk of injury to health or the environment, in which case the EPA must regulate those risks; (2) that there is insufficient information to make a reasoned evaluation of the chemical or SNU, in which case the agency must obtain additional information from the manufacturer; or (3) that the chemical or SNU is not likely to present an unreasonable risk.

In contrast, the European Union (EU) is implementing a comprehensive regulatory program for chemical substances, known as the Registration, Evaluation, Authorization, and Restriction of Chemical substances (REACH) program. REACH puts the responsibility for ensuring the safety of chemicals on the companies that produce, import, and use chemicals. The program applies to both new and existing chemicals, and is phased-in over an 11-year period based primarily on the production volume of individual chemicals. REACH employs a tiered-testing approach, with the amount of initial testing determined by production volume. A technical dossier is required for all registered chemicals; however, only chemicals with a production volume of 10 or more tons per year require a chemical safety assessment documented in a chemical safety report. REACH allows the use of alternative testing strategies to evaluate specific endpoints in lieu of experimental testing; however, whole animal testing requirements exist for each level based on production volume.

Hazardous Wastes The two primary statutes regulating hazardous wastes in the United States are the Resource Conservation and Recovery Act (RCRA, 1976) and the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, 1980). With some exceptions, the primary purpose of CERCLA is the cleanup of contamination from pre-existing hazardous waste sites, whereas RCRA regulates the generation, transport, and disposal of new hazardous wastes. Both RCRA and CERCLA have their own extensive lists of substances and waste streams of toxic materials that are defined as hazardous wastes. In addition, under RCRA, wastes that meet any of four "characteristics" are also treated as hazardous wastes. The four characteristics are ignitability, corrosivity, reactivity, and toxicity, and EPA has identified standardized protocols for determining whether a particular waste stream meets one or more of these characteristics. Under RCRA, EPA has developed standards for generators, transporters, and those who treat, store, or dispose hazardous wastes that are required to "protect human health and the environment." The EPA's regulations applicable to generators and transporters establish a manifest system that is designed to create a paper trail for every shipment of waste, from generator to final destination, to ensure proper handling and accountability. The agency has the broadest authority over persons who own or operate hazardous waste treatment, storage, or disposal facilities. Pursuant to the RCRA, it has issued regulations prescribing methods for treating, storing, and disposing of wastes; governing the location, design, and construction of facilities; mandating contingency plans to minimize negative impacts from such facilities; setting qualifications for ownership, training, and financial responsibility; and requiring permits for all such facilities (RCRA, 1976).

CERCLA, often referred to as Superfund, authorizes the cleanup of hazardous waste sites and provides for liability of persons responsible for releases of hazardous waste at these sites. EPA can conduct cleanup of hazardous waste sites itself, and then seek recovery for the costs from potentially responsible parties (PRPs), or it can direct one or more PRPs to conduct cleanup, who may then seek contribution from other PRPs for their share of the cleanup. Under CERCLA, EPA has created the National Priorities List (NPL), which is a list of hazardous waste sites that are deemed the most hazardous sites and eligible for use of federal funds for long-term cleanup, and the National Contingency Plan (NCP), which provides the guidelines and procedures needed to respond to releases and threatened releases of hazardous substances, pollutants, or contaminants. For sites on the NPL, EPA conducts a Remedial Investigation and Feasibility Study to support the risk management process, which includes a site-specific human health and ecological risk assessment.

Toxic Water Pollutants The EPA has had responsibility for regulating toxic water pollutants since 1972. As originally enacted, Section 307 of the Federal Water Pollution Control Act required the EPA to adopt standards for toxic water pollutants that provided an "*ample margin of safety*"—a difficult criterion to meet for most toxic pollutants and arguably impossible for any known to be carcinogenic. Given EPA's difficulties in complying with this statutory directive, Congress amended the statute in 1977 to focus standards on economic cost and technologic feasibility. In 1987, Congress amended the statute again to toughen standards for toxic pollutants. Under the prior law, the EPA had developed health-based "water quality criteria" for 126 compounds it had identified as toxic. These criteria essentially described *desirable* maximum contamination levels, which, because the EPA's discharge limits were technology-based, generally were substantially lower than the levels actually achieved. The 1987 amendments gave what had been advisory criteria real bite by requiring that states incorporate them in their own mandatory standards for water quality and impose additional effluent limits on operations discharging into below-standard waterways (Heineck, 1989).

Drinking Water The 1974 Safe Drinking Water Act (SDWA) was enacted to ensure that public water supply systems "meet minimum national standards for the protection of public health." Under the SDWA, the EPA is required to regulate any contaminants "which may have an adverse effect on human health." Over time and several Congressional amendments, this system has evolved into a two-tier system in which EPA adopts for each contaminant a maximum contaminant level goal (MCLG) that represents the optimal level to be achieved to ensure safety and the usually less stringent, feasibility-based maximum contaminant level (MCL). Only the MCL is legally enforceable. As part of the 1996 Safe Drinking Water Amendments, Congress directed EPA to use the "best available science" in setting MCLGs and MCLs.

Toxic Air Pollutants The original 1970 version of the Clean Air Act (CAA) provision for regulation of hazardous air pollutants (section 112) required the agency to set emission standards for individual toxic pollutants that protect public health with "an ample margin of safety." The implication of this language—that standards were to provide absolute safety without regard to the costs of emissions control—generated intense debate from the beginning and contributed to the EPA's glacial pace of implementation. The EPA finally attempted to escape the strict language of section 112 when it issued a standard for vinyl chloride in 1986 in which the agency claimed it could consider costs and declined to adopt a standard dictated solely by safety. A court ruled that the EPA had improperly considered costs, but it did make clear that in determining what emissions level was safe, even for a carcinogen, the EPA was not obligated to eliminate exposure but rather was to "decide what risks are acceptable in the world in which we live" (*NRDC v EPA*, 1987).

Amendments to the CAA in 1990 responded to the difficulties presented by the strict health-based approach of old section 112. The statute now provides a list of 188 hazardous air pollutants, which EPA may modify by adding or deleting items. The EPA must establish national emissions standards for sources that emit any of the listed pollutants with a two-tier system of regulation. The EPA must first issue standards that are technology-based, designed to require the "maximum achievable control technology" (MACT) [CAA § 112(d)(2)]. If the MACT controls are insufficient to protect human health with an "ample margin of safety," the EPA must issue residual risk standards [CAA § 112(f)]. The 1990 Amendments essentially define "ample margin of safety" for carcinogens by requiring the EPA to establish added residual risk limits for any

pollutant that poses a lifetime excess cancer risk of greater than one in one million. However, as subsequently clarified in a judicial decision, while EPA must promulgate residual risk standards if the MACT standards do not reduce risks to one in one million, the residual risk standards are not required to reduce the risks to one in one million, but rather to 100 in one million (*NRDC v EPA*, 2008).

Occupational Safety and Health Administration (OSHA)

The 1970 Occupational Safety and Health Act requires employers to provide employees with safe working conditions and empowers OSHA to prescribe mandatory occupational safety and health standards (OSHA, 1970). OSHA's most controversial actions involved its attempts to set occupational exposure limits for hazardous chemicals.

The Act specifies that in regulating hazardous occupational exposures, OSHA shall adopt the standard "which most adequately assures, to the extent feasible, on the basis of the best available evidence, that no employee will suffer material impairment of health or physical capacity" [OSHA § 6 (b)(5)]. Judicial challenges to OSHA standards have clarified OSHA's responsibilities. In a famous case, the U.S. Supreme Court overturned OSHA's benzene standard because the agency had not shown that prevailing worker exposure levels posed a "significant" health risk (*Industrial Union Department, AFL-CIO, v American Petroleum Institute*, 1980). This prerequisite proved a major obstacle when OSHA attempted to establish standards for 428 air contaminants in a single proceeding in 1989. Although it found that OSHA's generic approach to regulation was permissible in theory, a court vacated the standards because OSHA failed to show that each individual contaminant posed a "significant risk" at current levels (*American Federation of Labor v OSHA*, 1992). However, the Supreme Court earlier upheld OSHA's cotton dust standard, rejecting arguments that the agency was obligated to balance the costs of individual standards against the benefits of reducing hazardous workplace exposures (*American Textile Manufacturers Institute v Donovan*, 1982). The end result of these judicial challenges is that OSHA may adopt standards that reduce a "significant" risk to workers down to levels that are technologically and economically feasible, but cannot base its standards on a cost-benefit analysis.

OSHA promulgates substance-specific occupational exposure limits known as Permissible Exposure Limits (PELs), where compliance is measured with an 8-hour time-weighted average (TWA). For a few hazardous exposures (e.g., 1,3-butadiene, benzene, and ethylene oxide) OSHA has promulgated short-term exposure limits (STELs), which sets an average exposure limit for any 15-minute average that cannot be exceeded.

Another important standard promulgated and enforced by OSHA is the hazard communication standard (HCS). The HCS requires chemical manufacturers and importers to evaluate the hazards of the chemicals they produce or import, and prepare labels and material safety data sheets (MSDSs) to convey the hazard information to their downstream customers; and requires employers with hazardous chemicals in their workplaces to provide labels and MSDSs for their exposed workers, and train them to handle the chemicals appropriately. As of 2016, the HCS has been harmonized with the United Nations' (UN) Globally Harmonized System of Classification and Labeling of Chemicals (GHS). OSHA has provided detailed criteria in Appendix A to §1910.1200—Health Hazard Criteria for determining whether a substance is hazardous under the HCS. For example, any substance listed in the National Toxicology Program (NTP) "Report on Carcinogens" (latest edition) or the International Agency for Research on Cancer (IARC) "Monographs on the Evaluation of Carcinogenic Risks to Humans" will be considered a carcinogen or possible carcinogen under the HCS.

In addition to the HCS and substance-specific exposure limits, OSHA also enforces more generic standards such as the general duty clause, the particles otherwise not regulated (total dust) standard, and the respiratory protection standard. Unlike EPA, OSHA does not have authority to require chemical safety testing.

Other organizations also issue occupational exposure limits, but unlike OSHA, these standards are guidance and not legally enforceable. For example, the American Conference of Governmental Industrial Hygienists (ACGIH) publishes recommended but nonenforceable exposure standards known as threshold limit values (TLVs) which can be for an 8-hour time-weighted average exposure (TLV-TWA) or a 15-minute short-term time-weighted average (TLV-STEL). The TLV is a level that a worker can be exposed to day after day for a working lifetime without adverse effects. In addition, ACGIH also publishes threshold limit value–Ceiling limit (TLV-C) which is an absolute exposure limit that should not be exceeded at any time. The National Institute of Occupational Safety and Health (NIOSH) also publishes some Recommended Exposure Limits or RELs (although as of January 2017, NIOSH recommends a new value for carcinogens known as a Risk Management Limit for Carcinogens, or RML-CA).

Consumer Product Safety Commission (CPSC)

Of the four agencies discussed here, the CPSC has played the least important role in federal efforts to control toxic chemicals to date. The commission was created in 1972 by the Consumer Product Safety Act (CPSA, 1972) with authority to regulate products that pose an unreasonable risk of injury or illness to consumers. The commission is empowered to promulgate safety standards "to prevent or reduce an unreasonable risk of injury" associated with a consumer product. If no feasible standard "would adequately protect the public from the unreasonable risk of injury" posed by a consumer product, the commission may ban the product [CPSA § 8]. In assessing the need for a standard or ban, the agency must balance the likelihood that a product will cause harm, and the severity of harm it will likely cause, against the effects of reducing the risk on the product's utility, cost, and availability to consumers.

The CPSC also administers the older Federal Hazardous Substances Act (FHSA, 1976). The FHSA authorizes the CPSC to regulate, primarily through prescribed label warnings, products that are toxic, corrosive, combustible, or radioactive or that generate pressure. The FHSA is unusual among federal health laws because it contains detailed criteria for determining toxicity. It defines "highly toxic" in terms of a substance's acute effects in specified tests in rodents; substances capable of producing chronic effects thus fall within the "toxic" category. The FHSA contains another unique provision [FHSA § 2(h)(2)] specifically addressing the probative weight of animal and human data on acute toxicity: "If the [commission] finds that available data on human experience with any substance indicates results different from those obtained on animals in the above-named dosages or concentrations, the human data shall take precedence."

The CPSC has prescribed labeling for products containing numerous substances that are acutely toxic. It has also acted to ban from consumer products several substances that pose a cancer risk, including asbestos, vinyl chloride as a propellant, benzene, tris(hydroxymethyl)aminomethane, and formaldehyde (Merrill, 1981).

In 2008, Congress adopted the Consumer Product Safety Improvement Act (2008), which significantly strengthened the CPSC's enforcement authority, especially for children's products, in response to a number of high-profile recalls of children's toys. The Act imposes bans on products containing lead or phthalates that exceed stringent levels, and requires third-party testing of certain children's products.

INSTITUTIONAL OVERSIGHT AND CONTROLS

As the previous subsection describes, regulatory agencies are required to evaluate and apply toxicological and other scientific data in a variety of statutory contexts. In addition to the statutory language, a number of internal and external institutional control mechanisms and processes greatly influence the agencies' treatment of toxicological data.

Advisory Committees

Regulatory agencies frequently rely on scientific advisory committees composed of external scientific experts to help guide their scientific determinations, including toxicological evaluations. For example, the EPA has a Scientific Advisory Board (SAB), established by Congress in 1978, to advise the agency on the quality and relevance of the scientific and technical information being used in regulatory programs as well as to review the agency's research programs. The SAB's work is done by a relatively large number of subcommittees and panels that focus on special subjects. The EPA also has two other independent scientific advisory committees associated with specific regulatory programs—the Clean Air Science Advisory Committee for air pollution, and the Science Advisory Panel for pesticides. These committees consist of external scientists who are appointed to serve on the committees for specified terms. Similarly, the FDA has over 50 external advisory committees that provide advice on the agency's significant product approvals and other scientific issues.

Regulatory agencies are not required to automatically follow the advice of their external advisory committees, but frequently do. Failure to follow the independent advice of their own advisory committee tends to call into question the soundness of the agency's scientific findings, whereas advisory committee endorsement of the agency's position can provide important scientific credibility and political cover to the agency.

Peer Review

Beyond peer review by agency advisory committees, regulatory agencies frequently utilize external peer review of scientific reports and assessments. In December 2004, the Office of Management and Budget (OMB) formalized the requirement for peer review by issuing its Final Information Quality Bulletin for Peer Review (OMB, 2004). This Peer Review Bulletin requires federal regulatory agencies to ensure that all "influential scientific information" they disseminate is peer-reviewed. Influential scientific information is defined as "scientific information the agency reasonably can determine will have or does have a clear and substantial impact on important public policies or private sector decisions." The Bulletin specifically identifies "scientific assessments" as one type of information subject to the peer review requirement, which are defined as "an evaluation of a body of scientific or technical knowledge, which typically synthesizes multiple factual inputs, data, models, assumptions, and/or applies best professional judgment to bridge uncertainties in the available information." These assessments include, but are not limited to, state-of-science reports; technology assessments; weight-of-evidence analyses; meta-analyses; health, safety, or ecological risk assessments; toxicological characterizations of substances; integrated assessment models; hazard determinations; or exposure assessments.

The Peer Review Bulletin directs agencies to choose a peer review mechanism that is appropriate and commensurate with how the information will be used, giving due consideration to the novelty and complexity of the science involved, the relevance of the information to regulatory decision-making, the extent of prior peer reviews, and the expected benefits and costs of additional review. The Peer Review Bulletin requires the most rigorous peer review requirements for highly influential scientific assessments.

Risk Assessment Guidance/Guidelines

Regulatory agencies often adopt guidelines to promote consistency and predictability in their treatment of toxicological data and the conduct of risk assessment. For example, EPA has adopted risk assessment guidelines for carcinogenicity, mutagenicity, developmental toxicity, chemical mixtures, exposure analysis, reproductive toxicity, neurotoxicity, and ecotoxicity. The genesis of EPA's risk assessment guidelines was a series of "cancer principles" prepared largely at the instigation of EPA lawyers in the mid-1970s (Albert, 1994). The agency lawyers were frustrated by the delays in regulating pesticides as a result of scientific disagreement about the mechanisms and causes of human cancer. In an attempt to circumvent such scientific disputes, the lawyers developed a series of 17 "cancer principles" with the assistance of EPA scientists during hearings on the pesticides heptachlor and chlordane. The 17 principles were intended to be nonrebuttable guidelines that would govern and simplify carcinogenicity determinations.

Shortly thereafter, EPA began to develop a more comprehensive set of guidelines for evaluating carcinogens. This led to EPA publishing its "interim" guidelines for carcinogenic risk assessment in 1976, which were subsequently updated and finalized in 1986 (EPA, 1986). The 1986 guidelines primarily consisted of a series of "default options" that were intended as presumptive principles that would apply in the absence of sufficient data to establish an alternative assumption. Some of the most important default options included in EPA's 1986 carcinogen guidelines are: (i) laboratory animals are assumed to be a valid surrogate for humans in assessing risk; thus, positive cancer results in animal bioassays are taken as evidence of human carcinogenicity; (ii) humans are assumed to be as sensitive as the most sensitive animal species, strain, or sex evaluated in an appropriately designed animal bioassay; (iii) benign tumors are assumed to be as significant as malignant tumors; (iv) the dose–response of humans to potential carcinogens is assumed to be linear all the way to the zero exposure levels with no threshold; and (v) a given intake of a substance is assumed to have the same effect regardless of the rate or route of intake (EPA, 1986). Most of the default options selected by EPA were deliberately chosen to be "conservative," in that they are intended to estimate the plausible upper-bound of actual risk (NRC, 1994).

EPA's risk assessment guidelines not only promoted consistency in risk assessment approach and procedure across the broad array of EPA regulatory programs, which use risk assessment, but also furthered the objective of efficiency, by sparing the agency the need to revisit the same controversial issues in each successive rulemaking proceeding (Wiltse and Dellarco, 1996). The courts were generally supportive of the predictability and consistency provided by the agency's risk assessment guidelines, giving greater deference

to EPA risk assessments that comported with the guidelines. As one court stated, "EPA's specific enunciation of its underlying analytical principles, derived from its experience in the area, yields meaningful notice and dialogue, enhances the administrative process, and furthers reasoned agency decision making" (*Environmental Defense Fund, Inc, v Environmental Protection Agency*, 1976).

Notwithstanding these benefits of risk assessment guidelines, EPA's implementation of its guidelines was criticized in a 1994 NRC report that found that EPA applied the default principles too rigidly and had failed to articulate clear criteria for departing from the defaults (NRC, 1994). EPA itself acknowledged that "[i]n practice, the agency's assessments routinely have employed defaults and, until recently, only occasionally departed from them" (EPA, 1996). EPA published draft revisions to its carcinogen guidelines in 1996 (EPA, 1996) that were finalized in 2005 (EPA, 2005), which take a more flexible, data-based approach to default options. As explained by EPA, the revised guidelines "are intended to be both explicit and more flexible than in the past concerning the basis for making departures from defaults, recognizing that expert judgment and peer review are essential elements of the process" (EPA, 1996). The revised guidelines incorporate "a weight-of-the-evidence approach that considers all relevant data in reaching conclusions about the potential human carcinogenicity of an agent" (EPA, 1996). In 2014, EPA published "Framework for Human Health Risk Assessment to Inform Decision Making," which adopts a framework for risk-based decision-making that maximizes the utility of risk assessment (EPA, 2014).

Judicial Review

Agency regulations are often subject to legal challenges by stakeholders who disagree with the agency's decision. Under the Administrative Procedure Act, such judicial review tends to be deferential to the agency's decision, overturning the decision only if it is "arbitrary and capricious" or lacking "substantial evidence." Nevertheless, a significant proportion of major agency regulations are overturned in whole or in part, or sent back to the agency for further explanation. Scientific determinations, such as toxicological findings, are generally given the highest level of deference under a decision by the U.S. Supreme Court, which held that "[w]hen examining this kind of scientific determination, as opposed to simple findings of fact, a reviewing court must generally be at its most deferential" (*Baltimore Gas & Elec v NRDC*, 1983).

Even with this deference to scientific determinations, there have been many important judicial decisions impacting the way regulatory agencies address toxicological information. One prominent example was a challenge to the EPA's decision to retain an MCLG of zero under the Safe Drinking Water Act for chloroform in the face of evidence, accepted by its own scientific advisory committee, that the mechanism by which chloroform produces tumors in rodents is threshold-limited. The reviewing court held that given its acceptance of the evidence of a threshold, the EPA was required by the SDWA's "best available" evidence provision to base its decision on that evidence (*Chlorine Chemistry Council v EPA*, 2000). This ruling marks the first time that a court has directed a federal regulatory agency to recognize a "safe" finite level of exposure for an animal carcinogen. Another example of proactive judicial oversight is two recent decisions where the court second-guessed EPA's determination that there was sufficient toxicological evidence to justify departing from the presumptive 10-fold extra safety factor to protect children in pesticide regulatory decisions (*Northwest Coalition for Alternatives to Pesticides v EPA*, 2008; *NRDC v EPA*, 2011).

Congressional Oversight

Congress has ultimate oversight of regulatory agencies, both by delegating the authority to regulate in the form of statutes, and by controlling the purse strings for the agencies. Regulatory statutes determine many of the fundamental choices for regulatory programs by specifying what factors may be considered in adopting regulatory standards and the objectives of the standards in terms of the level of safety to be attained. Statutes differ greatly on these questions, with some mandating standards being based on technological feasibility, whereas others specifying health-based regulation. The statutes can provide additional guidance that can influence the agency's consideration of toxicological evidence, such as the 1996 amendments to the Safe Drinking Water Act, which direct EPA to use "the best available, peer-reviewed science and supporting studies conducted in accordance with sound and objective scientific practices" (Safe Drinking Water Act, 1996).

Congress also controls regulatory programs through its budgetary authority. By controlling how much money is directed to specific activities or programs, Congress can directly influence agency priorities and emphasis. If Congress is not pleased with an agency's actions, it can adopt appropriation riders prohibiting the agency from spending money on controversial topics. In the past, for example, Congress has prevented EPA from working on climate change or radiofrequency issues by imposing annual riders for a time period.

In addition to these primary legislative controls, Congress has a number of other ways it can influence agency decision-making. Congress can pressure agencies toward a preferred policy outcome through oversight hearings, letters to agency officials, and press releases. Congress has also adopted some oversight statutes to further control agency rulemaking. The Congressional Review Act requires federal regulatory agencies to file final rules with Congress before the rules can become effective. If the regulation meets the definition of a major rule ($100-million impact on the economy), Congress has 60 days to introduce a resolution of disapproval that, if adopted by both the House and Senate, can nullify the agency's rule, unless vetoed by the President. If a disapproval resolution is enacted, the rule may not take effect and the agency may issue no substantially similar rule without subsequent statutory authorization. The Congressional Review Act was only used once prior to 2017 to disapprove an agency regulation (OSHA ergonomic standard in 2001), the U.S. Congress has used this authority to disapprove more than ten agency rules in the first half of 2017.

Congress also enacted section 515 of the Treasury and General Government Appropriations Act of 2001, known as the Information Quality Act (IQA), which required the Office of Management and Budget (OMB) to promulgate guidance to agencies ensuring the quality, objectivity, utility, and integrity of information (including statistical information) disseminated by federal agencies (IQA, 2001). Federal agencies were also required by the IQA to publish their own agency-specific guidelines no later than 1 year after OMB's guidelines, and also provide a mechanism for stakeholders to file petitions challenging agency actions that allegedly fail to comply with the data quality objectives. Private parties have challenged a number of scientific determinations by federal agencies under this provision, but the courts have determined that the agency decisions on these petitions are not judicially reviewable (*Salt Institute v Leavitt*, 2006).

Executive Oversight

The Executive branch also exerts overview of regulatory decisions, particularly through the Office of Information and Regulatory Affairs (OIRA) within the White House OMB. OIRA reviews all

draft significant regulations proposed by regulatory agencies, and although its review most often focuses on the economic aspects of the proposed rule, it also reviews the agency's scientific assumptions and findings. Although OIRA cannot itself revise the proposed regulation, it can hold up its publication until it has reached agreement with the agency on acceptable revisions.

The Executive Branch has other mechanisms for oversight and influence of regulatory science determinations by agencies. The White House under various Presidents has put out a series of Executive Orders providing regulatory guidance that agencies must follow to the extent consistent with the governing regulatory statute. For example, Executive Order 13563 issued by President Obama in January 2011 requires that federal regulations "must be based on the best available science. It must allow for public participation and an open exchange of ideas. It must promote predictability and reduce uncertainty. It must identify and use the best, most innovative, and least burdensome tools for achieving regulatory ends. It must take into account benefits and costs, both quantitative and qualitative" (EO 13563, 2011).

The White House also issued a memorandum on Scientific Integrity in 2009 that required each regulatory agency to develop its own scientific integrity policy that implemented several principles of scientific integrity, including: "(a) The selection and retention of candidates for science and technology positions in the executive branch should be based on the candidate's knowledge, credentials, experience, and integrity; (b) Each agency should have appropriate rules and procedures to ensure the integrity of the scientific process within the agency; (c) When scientific or technological information is considered in policy decisions, the information should be subject to well-established scientific processes, including peer review where appropriate, and each agency should appropriately and accurately reflect that information in complying with and applying relevant statutory standards …" (White House, 2009).

REGULATORY INFLUENCES ON TOXICOLOGY

This chapter has focused thus far on how toxicological data are used in federal regulatory programs. Yet, the relationship between regulation and toxicology is reciprocal, in that regulatory programs have also shaped and influenced the practice of toxicology. Modern toxicology has developed, in substantial part, in response to the information needs of contemporary regulation. But government regulation impinges on the discipline of toxicology in more direct ways as well. Regulatory agencies often prescribe the specific objectives and design of studies that are conducted to satisfy regulatory requirements. In addition, pressure to protect animals used in research has produced laws and regulations that govern toxicologists themselves.

Testing Guidelines

An agency's influence over the conduct of toxicology studies depends on its regulatory responsibilities. An agency such as the FDA or the EPA, which must confirm the safety of new substances before marketing, can dictate the kinds of tests that manufacturers must conduct to gain approval. By contrast, an agency or program that has no premarket approval function has less leverage.

Agencies such as the FDA and EPA that have been authorized to require premarket approval for certain categories of products have generally specified the types of tests they require before they will consider the safety of a compound (e.g., tests for acute toxicity, subchronic effects, and chronic effects). Within each of these categories, an agency might set out more detailed requirements, essentially enumerating its "base set" data demands. In addition, the agencies usually adopt guidelines that describe preferred or acceptable methods for executing particular tests, such as a bioassay for carcinogenesis (FDA, 2000; EPA, 2011a). In addition, the EPA has established guidelines for several of the tests that it may mandate by rule or consent agreement for individual chemicals under TSCA § 4 (EPA, 2011a). Multinational bodies such as the Organization for Economic Cooperation and Development have sought to secure multilateral adherence to standardized test guidelines and minimum testing requirements for new chemicals (Page, 1982).

Both the FDA and the EPA have adopted another set of requirements that specify laboratory procedures for conducting tests required or submitted for regulatory consideration. These GLP regulations prescribe essential but often mundane features of sound laboratory science, such as animal husbandry standards and record-keeping practices (EPA, 2011b, 2011c; FDA, 2011a). The GLP regulations including requirements for (i) organization and personnel responsibilities (e.g., study director should be "a scientist or other professional of appropriate education, training, and experience, or combination thereof"); (ii) a quality assurance program; (iii) facilities; (iv) equipment, reagents, and materials; (v) test systems; (vi) test and reference items; (vii) standard operating procedures; (viii) performance of study; (ix) reporting of results; and (x) archival storage of records and reports. All of these requirements are intended to contribute to sound regulatory decision-making by ensuring the quality and integrity of toxicology data submitted to support agency decisions.

Food and Drug Administration The FDA exercises premarketing approval authority over several classes of compounds, of which the most important, for present purposes, are new human drugs and direct additives to food.

Toxicology Testing Requirements for Human Drugs In 1962, Congress expressly authorized the FDA to exempt investigational drugs from the premarket approval requirement so that they could be shipped for use in clinical testing, subject to conditions the agency believed appropriate to protect human subjects [FFD&C Act § 505(i)]. One condition that the FDA established was that an investigational drug first must have been evaluated in preclinical studies, which are then submitted to FDA as an Investigational New Drug (IND) application. This requirement appears in current regulations that amplify, in the text and in referenced guidelines, the types of tests that are to be performed and the design they should follow (FDA, 2011b). A drug's sponsor is encouraged to consult agency personnel to get a precise understanding of what sorts of toxicology studies the agency expects prior to submitting the IND. Preclinical studies of substances that are candidates for use as human drugs must also meet the standards set by the FDA's GLP regulations (FDA, 2011a). These regulations apply to all laboratories—university, independent, and manufacturer-owned—in which such studies are conducted. The work of the International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) highlights the trend toward international agreement on test methods. Since its founding in 1990, the ICH—comprising the pharmaceutical regulatory agencies and industries from the European Union, Japan, and the United States—has issued over 50 harmonized guidelines on various aspects of pharmaceutical regulatory approval, including numerous guidelines on toxicology testing methods for human drugs.

Testing Requirements for Food Additives The Food Additives Amendment and the Color Additive Amendments require premarket approval of new additives to human food. Both laws

assume that laboratory studies in animals will provide the principal data for assessing safety. Thus, a petitioner must submit "full reports of investigations made with respect to the safety for use of such additives, including full information as to the methods and control used" [FFD&C Act § 409(c)]. The FDA has adopted regulations specifying the types of data that an applicant must submit (FDA, 2011c).

The FDA's regulations contain only general statements about the need for and features of toxicology studies. For many years, the agency maintained an advice-giving system in which it prescribed the type and design of tests to be performed. In 1982, the FDA first codified this "common law" in *Toxicological Principles for the Safety Assessment of Direct Food Additives and Color Additives Used in Food,* known thereafter as the "Red Book." The Red Book, revised in 2000, describes the types of tests the FDA believes necessary to evaluate an additive's safety (FDA, 2000). The agency's requirements, which are in the form of guidelines rather than regulations, are calibrated to the purposes for which the additive will be used, to estimated levels of human exposure, and to the results of sequential studies. Tests of food color and additives must also comply with the FDA's GLP regulations (FDA, 2011a).

Environmental Protection Agency The EPA's premarket approval authority over pesticides places it, like the FDA, in a position to dictate the design and conduct of studies on such compounds. The 1976 TSCA gave the EPA authority to mandate testing of other chemicals in use or scheduled for introduction and to specify, by regulation, test standards.

Toxicology Requirements for Pesticides The Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) requires the submission of toxicology studies, as well as other types of investigations, to support the EPA's evaluation of a pesticide [FIFRA § 136(b)]. The statute also requires the EPA to publish guidelines specifying the kinds of information that will be required to support the registration.

The agency has issued regulations outlining the procedures for submission of registration petitions and their basic content (40 CFR part 158 and 161). The Office of Chemical Safety and Pollution Prevention (formerly the Office of Prevention, Pesticides, and Toxic Substances) has issued Harmonized Test Guidelines for all toxicology testing done under both FIFRA (pesticides) and TSCA (chemicals) (EPA, 2011a). For example, the Health Effects Test Guidelines (Series 870) include guidelines for approximately 50 different specific assays for acute toxicity, subchronic toxicity, chronic toxicity, genetic toxicity, neurotoxicity, and other toxicity testing. EPA has attempted to harmonize these guidelines whenever possible with applicable Organization for Economic Cooperation and Development (OECD) guidelines. Animal studies of pesticides must also comply with EPA's own GLP regulations, which were inspired by the same investigations that led the FDA to promulgate its standards for testing laboratories and impose similar requirements.

Testing of Industrial Chemicals The primary means by which the EPA may mandate health effects testing of new or existing industrial chemicals is Section 4(a) of the TSCA. Prior to the 2016 amendments to the TSCA (TSCA, 2016), the agency was required to promulgate a regulation to require testing of a specific compound, but the 2016 amendments provide more flexibility and allow EPA to also require testing by administrative order. This obligation to order testing is triggered by an administrative finding that a chemical presents a potential risk (based on the suspicion of toxicity) or that humans or the environment will be exposed to substantial quantities. The statute creates an Interagency Testing Committee (ITC) with members from EPA, CPSC, FDA, Department of the Interior (DOI), OSHA, Council on Environmental Quality (CEQ), National Institute for Occupational Safety and Health (NIOSH), National Institute of Environmental Health Sciences (NIEHS), National Cancer Institute (NCI), National Science Foundation (NSF), Agency for Toxic Substances and Disease Registry (ATSDR), National Library of Medicine (NLM), USDA, and the Department of Commerce to recommend a list of chemicals that should be tested and in what order of priority. Once the ITC has recommended a chemical substance for testing, the EPA is required by statute to either initiate testing or publish its reasons for not doing so within 12 months, although given the administrative burdens of such action the agency has frequently failed to meet this deadline.

Validation of Alternative Test Methods

Regulatory agencies have also been instrumental in encouraging the development of new safety test methods. Federal agency validation of new toxicological test methods was formalized and harmonized by the Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) Authorization Act of 2000, which permanently established the ICCVAM. Some 15 federal agencies participate in ICCVAM. Congress directed that one of the purposes of ICCVAM was to "ensure that new and revised test methods are validated to meet the needs of Federal agencies" [Pub L 106-545, §3(b)(4)]. In that regard, ICCVAM is directed to review and evaluate new or revised or alternative test methods and to provide test recommendations to federal agencies. Each federal agency administering a program that "requires or recommends acute or chronic toxicological testing" is required to adopt an alternative test method recommended by ICCVAM unless the agency determines that the alternative test method would not be consistent with its statutory goals.

The ICCVAM statute also requires that each federal agency "that requires or recommends acute or chronic toxicological testing shall ensure that any new or revised acute or chronic toxicity test method, including animal test methods and alternatives, is determined to be valid for its proposed use prior to requiring, recommending, or encouraging the application of such test method" [Pub L 106-545, §4(c)]. ICCVAM has established detailed criteria for the validation and regulatory acceptance of toxicological test methods (NIEHS, 1997). ICCVAM defines validation as "the process by which the reliability and relevance of a test method are evaluated for the purpose of supporting a specific use." The ICCVAM criteria stipulate that test methods that have been validated according to the ICCVAM criteria are not automatically acceptable for regulatory agencies. The ICCVAM criteria thus specify a second set of criteria for regulatory acceptance, which address the existence of standard operating procedures for the test method, its cost-effectiveness, its utility for agency risk assessment, its potential for harmonization with similar testing requirements by other entities, and its potential for reducing the use of animals. The ICCVAM statute preserves the individual agency's final authority to accept or reject a specific test method based on its statutory mandate and regulatory mission.

The ICCVAM process has now been used to validate a significant number of alternative test methods, including for acute oral toxicity, dermal irritation, acute inhalation toxicity, endocrine disruptors, biologics testing, genetic toxicity, ecotoxicity, ocular irritation, allergic contact dermatitis, and reproductive and developmental toxicity. The ICCVAM Authorization Act also directs federal agencies to reduce, refine, and/or replace the use of animals in testing where feasible.

Computational Toxicology

Another area where regulatory demands and programs are pushing the development of new toxicology tests is the field of computational toxicology. Computational toxicology uses high-powered

computers to discern patterns and findings from large data sets derived from quantitative structure–activity relationships, in vitro assays, and various 'omic technologies (e.g., toxicogenomics, proteomics, and metabolomics). The regulatory driver for computational toxicology is the need to evaluate much larger numbers of chemicals much quicker and at lower costs, and perhaps eventually even with more robust and relevant results, than traditional animal studies. The shift toward computational toxicology was boosted by a 2007 Natural Research Council report entitled *Toxicity Testing in the 21st Century: A Vision and a Strategy*, which endorsed greater reliance on computational methods (NRC, 2007). EPA has launched an ambitious program to implement computational methods into its regulatory programs, which is called the ToxCast program. The ToxCast program has so far screened over 1800 chemicals using over 700 high-throughput assays that cover a range of high-level cell responses and approximately 300 signaling pathways.

In 2008, EPA and the National Institutes of Health (NIH) signed a memorandum of agreement to work together to develop these new toxicological methods for regulatory applications (Collins et al., 2008), which grew into an inter-agency collaboration called Toxicology in the 21st century (Tox21). This federal collaboration among EPA, NIH, including National Center for Advancing Translational Sciences and the National Toxicology Program at the National Institute of Environmental Health Sciences, and the Food and Drug Administration, has the objective of developing better toxicity assessment methods to quickly and efficiently test whether certain chemical compounds have the potential to disrupt processes in the human body that may lead to negative health effects. Using a high-throughput robotic screening system, the program is screening 10,000 environmental chemicals (called the Tox21 10K library) for their potential to disrupt biological pathways that may result in toxicity.

Animal Welfare Requirements

Researchers who conduct studies funded by federal agencies must comply with the Animal Welfare Act (AWA), and some are also subject to restrictions imposed by the Public Health Service (PHS). Recipients of grants from the Department of Education, the Department of Agriculture, or the EPA are subject only to the AWA. Those funded by the Department of Energy or by the PHS (which includes all research agencies within the Department of Health and Human Services, including the NIH) must also comply with PHS policies. Restrictions on animal use also appear in the GLP regulations adopted by the FDA and the EPA (Reagan, 1986).

Animal Welfare Act The AWA was initially adopted in 1966 and has been subsequently amended several times (1970, 1976, 1985, 1990, 2002, 2007, and 2008). It is administered by the Animal and Plant Health Inspection Service (APHIS), a part of the USDA. The AWA, which protects only warm-blooded animals and excludes birds, rats, and mice bred for research, requires all covered research facilities to register with APHIS and agree to comply with applicable AWA standards for humane treatment of animals. Each facility must file an annual report signed by a responsible official that shows that "professionally acceptable standards governing the care, treatment, and use of animals" were followed for the year in question (Animal Welfare Act, 1988).

Pursuant to the AWA, APHIS has established specific requirements for the humane handling, care, and transportation of dogs and cats, guinea pigs and hamsters, rabbits, nonhuman primates, marine mammals, and other warm-blooded animals. The regulations governing facilities address living space, heating, lighting, ventilation, and drainage. The health and husbandry provisions address feeding, watering, sanitation, veterinary care, grouping of animals, and the number and qualifications of caretakers (APHIS, 2011).

The AWA requires each research facility to establish an Institutional Animal Care and Use Committee (IACUC), composed of three or more members, one of whom must be a veterinarian and one of whom must represent community interests and who may not be affiliated with the institution. In 1989, the APHIS expanded the responsibilities of the IACUC and increased the minimum size to five members, and must include a veterinarian, an animal research scientist, a nonscientist, and an individual not affiliated with the institution. At least one member of the IACUC must now review and approve the animal care and use components of all proposed research activities. Prerequisites to approval include the avoidance or minimization of discomfort, distress, and pain; the use of pain-relieving drugs where appropriate; the consideration of pain-free alternatives; and euthanization when an animal would otherwise experience severe or chronic pain or distress that cannot be relieved.

The IACUC is also responsible for conducting semiannual inspections of the facility itself and of the program for humane care and use of animals. Committee reports are filed with the APHIS and with any federal agency funding the research.

Public Health Service Policy The PHS Policy on Humane Care and Use of Laboratory Animals applies to research funded by the NIH and other federal agencies that uses any vertebrate animals, and thus has a broader reach than the AWA. The PHS policy requires each facility to submit an annual report, called an "Assurance," which is evaluated by the NIH Office of Laboratory Animal Welfare (OLAW) to determine the sufficiency of animal care.

The PHS policy imposes two primary obligations on researchers as a condition for receiving federal funding: each institution must adopt an Institutional Program for Animal Care and Use, and it must establish an IACUC. The IACUC must review all applications for research funding and review the institution's programs to ensure compliance with NIH standards. The Health Research Extension Act of 1985 requires that PHS-funded institutions provide training on methods to reduce animal suffering similar to that mandated by the AWA for its personnel. It also requires that researchers' grant applications justify any proposed use of animals (NRC, 1988).

Research facilities subject to either the AWA or PHS may wish to consult a National Academy of Sciences' report that details suggestions for developing institutional compliance programs (NRC, 1991). Scientists working with no federal funding who expect their research to be submitted to the FDA or the EPA are not subject to the AWA or PHS policies, but they must comply with the animal protection provisions of those agencies' GLP regulations. These regulations prescribe adequate living conditions, detail requirements for veterinary treatment, and impose specific record-keeping requirements (EPA, 2011b, 2011c; FDA, 2011a).
